'he Publishers and the Editor-in-Chief will be grateful to readers
; volume who will kindly call attention to any errors of omission
imission therein. It is intended to make our publications stand
:ks of study and reference, and, to that end, the greatest accuracy
ght. It rarely happens that the early editions of books are free fro
ors; but it is the endeavor of the Publishers to have them remove
l it is therefore desired that the Editor-in-Chief may be aided in hi
k of revision, from time to time, by the kindly criticism of readers.

JOHN WILEY & SONS, INC.
432 Fourth Avenue, New York.

First Edition printed in
September, 1914

Composition and Electrotyping by the STANHOPE PRESS, Boston, Mass.
Printing and Binding by BRAUNWORTH & COMPANY, Brooklyn, N.Y.

PREFACE

PREFACE

In the summer of 1910 the writer was invited by the publishers of Kent's *Mechanical Engineers' Pocket-Book* and of the *American Civil Engineers' Pocket-Book* (Mansfield Merriman, Editor-in-Chief), to act as Editor-in-Chief of a Handbook of Electrical Engineering. Although there were at that time two electrical engineering handbooks in general use in this country, it seemed that a new handbook of electrical engineering, treating in a somewhat different manner the various subjects which naturally come within the scope of such a reference book, would fill a want felt by both practicing engineers and students of engineering.

The Handbook here offered to the engineering profession embodies the following features:

1. The Handbook has been prepared primarily for the practicing engineer. With this end in view the matter has been so arranged as to be most readily found, and all *theoretical discussions have been segregated into separate articles.* It is fully realized that the practicing engineer sometimes is desirous of finding a clear and concise statement of fundamental principles and theory, but when he wants specific data or practical information he does not care to search through a maze of theoretical discussions. Consequently, in this book fundamental or "theoretical" principles are fully but concisely treated in articles dealing with such matters and nothing else, e.g., such articles as *Electricity and Magnetism, Principles of; Alternating Currents; Electrochemistry, Principles of; Mechanics, Principles of; Hydraulics; etc.* Therefore, in articles dealing with practical matters only enough is said of theory to indicate the general principle of which the matter in hand may be a specific application.

2. The Handbook is primarily for Electrical Engineers, but the general arrangement of the subject matter and the method of treatment adopted will make the book a useful reference book for mechanical, civil, mining and other engineers who have occasion to utilize any of the numerous applications of electricity in their special fields. Considerable space has been devoted to those matters pertaining to the applications of motors in all branches of modern industry; see the article on *Motors, Industrial Applications of,* and the numerous cross references there given.

3. Although the Handbook deals primarily with electrotechnical matters, a large amount of space has been devoted to those mechanical and civil engineering subjects which are closely related to electrical engineering practice. To an electrical engineer who is fortunate enough to possess a good mechanical engineer's handbook and a good civil engineer's handbook, this may seem a duplication of effort. However, young engineers at the beginning of their professional careers usually seem satisfied with a handbook covering only their particular "brand" of engineering. To such electrical engineers a concise treatment of the elements of mechanical and civil engineering should prove particularly helpful. Moreover, the convenience of having under one cover the essential mechanical and civil engineering data will prove a convenience even to those electrical engineers who may possess other reference books dealing with these matters in greater detail.

4. Numerous mathematical tables and relations are given in the Handbook. Among these may be mentioned the articles on *Logarithms, Trigonometric Functions, Hyperbolic Functions, Exponential Functions, Derivatives, Integrals, Indeterminate Forms, Equations,* etc. The table of trigonometric functions is

so arranged that the three functions, sine, cosine and tangent, of each tenth of a degree are given at one place on the page; this arrangement will be found particularly useful in alternating-current calculations, since usually at least two of these functions are needed simultaneously. The table of hyperbolic functions, together with a statement of the meaning of such functions and the various formulas used in their application, should prove valuable to those having to make calculations of long-distance power-transmission lines. The table of exponential functions will be found very useful in making calculations of transient electrical phenomena and also for other calculations in which ϵ^x or ϵ^{-x} occur.

5. In spite of the fact that this book contains upwards of 2000 pages, many of the articles have been greatly condensed. However, it has been the consistent endeavor of the editorial staff to make each article sufficiently complete so that the information given therein should be of the greatest practical value. A handbook is not a treatise, and one should therefore not expect to find such detail as is given in an ordinary textbook; yet, on the other hand, a reference book of this kind should contain enough explanation and examples to make clear the application of the data given. This idea has been kept in mind throughout.

6. Although this book has been prepared primarily for the practicing engineer, it is believed that the method of treatment adopted will render many of the articles suitable as the bases for courses of lectures in technical schools. A teacher usually has his own method of presenting a subject, and sometimes a textbook proves more of a handicap than a help; yet every teacher recognizes the desirability of putting in the hands of his students some sort of synopsis or syllabus which will serve as a general guide.

7. The encyclopedic arrangement of this book is a departure in handbook construction, but now that the book is completed the writer is more firmly convinced than ever that it is the rational arrangement. A handbook is a reference book. Therefore the object of any arrangement is to render the data given in the book readily accessible. Experience has shown that the alphabetical arrangement is eminently fitted for an encyclopedia of general information; a like arrangement is equally applicable to a reference book dealing only with engineering topics. The subject matter of this book has therefore been disposed of in articles. At the beginning of each article is given a list of references to related articles. Besides, there is a detailed index covering some 54 pages at the end of the book. The user of the book will undoubtedly find it more convenient at first to refer directly to this detailed index, but as soon as he becomes acquainted with the main article headings, he will be able to turn directly to the article containing the information he may be seeking without referring to the index.

8. One feature of this Handbook which should prove particularly helpful is that the same plan of treatment has been consistently followed in all the articles, at least wherever possible. This applies particularly to articles dealing with apparatus or machinery, the plan of treatment being:

a. General Description and Definitions.
b. Brief Statement of Application.
c. Principle of Operation.
d. Design.
e. Testing.
f. Performance.
g. Specifications.
h. Installation.
i. Operation.

some instances it was found advisable to vary this scheme more or less, the general sequence of topics was adhered to as closely as possible. At beginning of each article occupying more than fifteen pages is given a brief le of contents.

. It is believed that the cost data given in the various articles will prove ticularly valuable when properly used. These data in most instances are en as unit costs, and usually the ordinary *range* of cost is given. It has been experience of the writer that students and recent technical graduates are lly lacking in even the roughest idea of the cost of apparatus and structures. is primarily to supply a rough idea of such costs that the cost curves and ures are given in the various articles. The cost data given will also be found table for preliminary estimates; but for close estimating, current prices uld of course be obtained from the makers of the apparatus, or, in the case construction work, some one having personal experience in similar work uld be consulted.

10. The bibliography given at the end of each article is intended to direct e reader to more extended information in treatises and current periodicals. e space available for these bibliographies has made it necessary to omit any important works and technical articles The references are usually ose with which the writer of the article in question is most familiar and which has found most useful. They are therefore in no sense complete, but will be und a very useful guide in the search for additional information. In many nstances a blank space of a half page or more is left after the bibliography; this space may be advantageously utilized by the insertion of references to new books and articles as they appear.

11. The articles in this Handbook have been prepared by an editorial staff of experts; this staff is given on pp. III and IV. The name of the writer of each article is given at the end of the article.

12. The preparation of the various articles has extended over a period of approximately three years. However, none of the plates were cast until the summer of 1914. Before casting, all the galleys were carefully revised in order to bring the articles up-to-date, and in some instances large sections of the articles were rewritten. In particular, all the articles dealing with electrical apparatus and machinery were revised in July, 1914, to bring them into agreement with the new Standardization Rules of the American Institute of Electrical Engineers (see p. 1295), presented to the Board of Directors of the Institute on July 10, 1914.

The Editor-in-Chief wishes to take this opportunity of expressing his sincere appreciation of the hearty coöperation of the entire editorial staff. Naturally, to make the treatment of the various articles in a work of this kind uniform throughout, much rearrangement of material and modification in its original presentation has been necessary. Each associate editor has been quick to realize this point, and has been unsparing in his efforts to bring about a concise and uniform treatment of the various subjects covered in the book. To Mr. H. F. Thomson, who has acted as Assistant Editor during the past two years, the Editor-in-Chief is particularly indebted for valuable assistance throughout the most arduous part of the editorial work.

The writer also wishes to express the appreciation of the associate editors for the valuable assistance given by their personal friends, and by various engineering firms and manufacturing companies, in the preparation of the various articles.

The plate proof of the entire book has been carefully read by Mr. N. S. Marston of the Massachusetts Institute of Technology. He has done this work with extreme thoroughness, checking every formula and table either by direct calculation, or by reference to its original source. It is hoped that all serious errors have thus been eliminated.

In conclusion, the writer wishes to express his appreciation of the spirit of coöperation and generosity shown by the publishers throughout the preparation of this book.

HAROLD PENDER.

ABBREVIATIONS AND SYMBOLS. — (*See also Units and Conversion Factors.*) At the meeting of the International Electrotechnical Commission in Berlin, in 1913, a list of 36 symbols for electrotechnical and related quantities was adopted. The American Institute of Electrical Engineers has also adopted (1914) a list of such symbols, which for the most part is in agreement with the list of the I.E.C., but contains certain additional symbols not included in the I.E.C. list. In the following table both lists are given. See paragraph 495 of the *Standardization Rules of the A.I.E.E.* for symbols for photometric quantities.

STANDARD SYMBOLS AND ABBREVIATIONS

Name of quantity	Symbol for the quantity		Name of Unit, adopted by A.I.E.E.	Abbreviation for the unit to be used only after numerical values	
	Adopted by I.E.C. (*See Note 1*)	Adopted by A.I.E.E.		Adopted by I.E.C.	Adopted by A.I.E.E.
Acceleration due to gravity	g	g	centimeter per second per second	—	cm. per sec. per sec.
Acceleration due to gravity, Standard (=980.665 cm. per sec. per sec.) (*Note 5*)	—	g_0	centimeter per second per second	—	cm. per sec. per sec.
Admittance	—	Y, y	mho	—	—
Angles	α, β, γ, etc.	—	—	—	—
Angular velocity ($2\pi f$)	ω	ω	radian per second	—	—
Capacity (Capacitance)	C	C	farad	F	—
Conductance	G	g	mho	—	—
Conductivity (*Note 6*)	—	γ	mho per centimeter	—	mho per cm.
Current	I	I, i	ampere	A	—
Dielectric constant	ϵ	ϵ or k	—	—	—
Dielectric field intensity or electric force	—	F	—	—	—
Dielectric flux	—	ψ	—	—	—
Dielectric flux density	D	D	—	—	—
Efficiency	η	η	per cent	—	(*Note 7*)
Electromotive force (e.m.f.)	E	E, e	volt	V	—
Energy	W (U)	U or W	joule or watt-hour	—	—
Frequency	f (ν)	f	cycle per second	—	~
Impedance	Z ($\mathfrak{Z}$)	Z, z	ohm	(*Note 2*)	—
Inductance (or coefficient of self-induction)	L ($\mathfrak{L}$)	L	henry	H	—

STANDARD SYMBOLS AND ABBREVIATIONS (*Continued*)

Name of quantity	Symbol for the quantity: Adopted by I.E.C. (*See Note 1*)	Symbol for the quantity: Adopted by A.I.E.E.	Name of unit adopted by A.I.E.E.	Abbreviations for unit to be used after numerical values: Adopted by I.E.C.	Abbreviations for unit to be used after numerical values: Adopted by A.I.E.E.
Inductance, mutual (or coefficient of mutual induction)	M ($\mathfrak{M}$)	M	henry	H	—
Length	l (*Note 3*)	l	centimeter	cm.	cm.
Magnetic flux (*Note 4*)	Φ ($\mathcal{F}$)	Φ, ϕ	maxwell	—	—
Magnetic flux density	B ($\mathcal{B}$)	$B, \mathcal{B}$	gauss (*Note 4*)	—	—
Magnetization, intensity of	J ($\mathcal{J}$)	J	—	—	—
Magnetizing force or magnetic field intensity	H ($\mathcal{H}$)	$H, \mathcal{H}$	gilbert per centimeter or gauss	—	gilbert per cm.
Magnetomotive force (m.m.f.)	—	$\mathcal{F}$	gilbert (*Note 4*)	—	—
Mass	m (*Note 3*)	m	gram	—	g.
Period	T	—	—	—	—
Permeability	μ	μ	—	—	—
Phase displacement (or phase angle)	ϕ	θ, ϕ	degree or radian	—	(*Note 8*)
Potential difference (p.d.)	—	V, v or E, e	volt	V	—
Power	P	P, p	watt	W	—
Quantity of electricity	Q	Q, q	coulomb or ampere-hour	C	—
Reactance	X ($\mathfrak{X}$)	X, x	ohm	(*Note 2*)	—
Reluctance	S ($\mathcal{R}$)	$\mathcal{R}$	—	—	—
Resistance	R	R, r	ohm	(*Note 2*)	—
Resistivity (*Note 6*)	ρ	ρ	ohm-centimeter	—	ohm-cm.
Revolutions per unit time	n	n	revolution per second	—	rev. per sec.
Susceptance	—	b	mho	—	—
Susceptibility	κ	κ	—	—	—
Temperature, absolute	T, Θ	—	degree centigrade	—	—
Temperature, centigrade	$t (\theta, \vartheta)$	T, t, θ	degree centigrade	—	deg.cent. (*Note 8*)
Time	t (*Note 3*)	t	second	—	sec.
Turns or number of conductors	—	N	convolution or turn	—	—
Voltage	—	E, e or V, v	volt	V	—
Work, mechanical	A (W)	W or A	joule or watt-hour	—	—

NOTES. — (1) The symbols in brackets are recommended in case the principal symbol is unsuitable; instead of the script letters heavy-faced or other special type may be used. (2) One or other of the symbols O and Ω is recommended provisionally to represent the ohm. The symbol Ω should no longer be employed for the megohm. (3) In dimensional equations the capital letters L, M and T for length, mass and time respectively are to be employed. (4) An additional unit for m.m.f. is the "ampere-turn", for flux the "line", and for magnetic flux density "maxwell per sq. in." (5) This has been the accepted standard value for many years and was formerly considered to correspond accurately to 45° latitude and sea level. Later researches, however, have shown that the most reliable value for 45° and sea-level is slightly different; but this does not affect the standard value given above. (6) The numerical values of these quantities are *ohms resistance* and *mhos conductance* between two opposite faces of a cm. cube of the material in question, but the correct names are as given, not ohms and mhos per cm. cube as commonly stated. (7) The symbol % is commonly used for per cent, but is not recommended by the A.I.E.E. (8) The symbol ° is commonly used for degree, ° C. for degree centigrade and ° F. for degree Fahrenheit; these symbols are not recommended by the A.I.E.E.

In addition to the symbols for the units given in the above table, the I.E.C. adopted (1913) the following signs to be used only after numerical values.

Volt-coulomb	**VC**	Kilovolt-ampere	**kVA**
Watt-hour	**Wh**	Kilowatt-hour	**kWh**
Volt-ampere	**VA**	Sign for milli-	**m**
Ampere-hour	**Ah**	Sign for kilo-	**k**
Milliampere	**mA**	Sign for micro- or micr-	**μ**
Kilowatt	**kW**	Sign for mega- or meg-	**M**

SPECIAL RULES IN REGARD TO SYMBOLS. — The following rules were also adopted at the Berlin meeting (1913) of I.E.C., and are concurred in by the Standards Committee of the A.I.E.E. The latter committee also recommends that vector quantities be printed in bold-face capitals.

Instantaneous values of electrical quantities which vary with the time to be represented by small letters. In case of ambiguity they may be followed by the subscript "t."

Virtual (*i.e., effective or r.m.s.*) or constant values of electrical quantities to be represented by capital letters.

Maximum values of periodic electrical and magnetic quantities to be represented by capital letters followed by the subscript "m."

In cases where it is desirable to distinguish magnetic quantities from electric quantities, magnetic quantities should be represented by capital letters of either script, heavy-faced or other special type. Script letters should not be used except for magnetic quantities.

Angles should be represented by small Greek letters.

Dimensionless and specific quantities should be represented wherever possible by small Greek letters.

Ordinary numerals as exponentials shall exclusively be employed to represent powers. (In consequence, it is desirable that the expression $\sin^{-1}x$, $\tan^{-1}x$, employed in certain countries, be expressed by arc sin x, arc tan x.)

The comma and the full-stop shall be employed for separating decimals according to the custom of the country, but the separation between any three digits constituting a whole number shall be indicated by a space and not by a full-stop or a comma (1 000 000).

For the multiplication of numbers and geometric quantities indicated by two letters, it is recommended to use the sign × and the full-stop only when there is no possible ambiguity.

To indicate division in a formula it is recommended that the horizontal bar and the colon be employed. Nevertheless the oblique line may be used when

there is no possibility of ambiguity; when necessary, ordinary brackets ( ), square brackets [ ], and braces { } may be employed to obtain clearness.

INSTITUTE (A.I.E.E.) STYLE. — The Editing Committee of the American Institute of Electrical Engineers issues a little pamphlet called "Suggestions to Authors," in which are given the rules of the Institute in regard to manuscript submitted for publication. The following list of abbreviations is taken from the last edition (1913) of these rules.

Name	A.I.E.E. style	Name	A.I.E.E. style
Alternating current	spell out, or a-c. as adjective.	Kilowatts	kw.
		Kilowatt-hours	kw-hr.
		Magnetomotive force	m.m.f.
Amperes	spell out	Mean effective pressure	spell out
Brake horse power	b.h.p.	Miles	mi.
Boiler horse power	boiler h.p.	Miles per hour per second	mi. per hr. per sec.
British thermal units	B.t.u.		
Candle power	c.p.	Millimeters	mm.
Centigrade	cent.	Milligrams	mg.
Centimeters	cm.	Minutes	min.
Circular mils	cir. mils	Meters	m.
Counter electromotive force	counter e.m.f.	Meter-kilograms	m-kg.
		Microfarad	spell out
Cubic	cu.	Ohms	spell out
Diameter	spell out	Per	spell out
Direct current	spell out, or d-c. as adjective.	Percentage	per cent, or % in tabular matter.
Electric horse power	e.h.p.	Pounds	lb.
Electromotive force	e.m.f.	Power-factor	spell out
Fahrenheit	fahr.	Revolutions per minute	rev. per min., or r. p. m. in tabular matter.
Feet	ft.		
Foot-pounds	ft-lb.		
Gallons	gal.		
Grains	gr.	Seconds	sec.
Grams	g.	Square	sq.
Gram-calories	g-cal.	Square-root-of-mean-square	effective, or r.m.s.
High-pressure cylinder	spell out		
Hours	hr.	Ton-mile	spell out
Inches	in.	Tons	spell out
Indicated horse power	i.h.p.	Volts	spell out
Kilogram	kg.	Volt-amperes	spell out
Kilogram-meters	kg-m.	Watts	spell out
Kilogram-calories	kg-cal.	Watt-hours	watt-hr.
Kilometers	km.	Watts per candle power	watts per c.p.
Kilovolts	kv.	Yards	yd.
Kilovolt-amperes	kv-a.		

1. Use "Fig.," not "Figure." Example: "Fig. 3" and not "Figure 3."

2. In all decimal numbers having no units, a cipher should be placed before the decimal point. Example: "0.32 lb." not ".32 lb."

3. Use the word "by" instead of "x" in giving dimensions. Example: "8 by 12 in." not "8x12 in."

4. Never use the characters (′) and (″) to indicate either feet and inches, or minutes and seconds as period of time.

5. Do not use the expression "rotary" or "rotary converter"; use "converter" or "synchronous converter."

6. Do not use a descriptive adjective as a synonym for the noun described. Example: a "spare transformer," not a "spare"; a "portable instrument," not a "portable"; "automatic apparatus," not "automatics"; a "short circuit," not a "short."

7. Do not use the words "primary" and "secondary" in connection with transformer windings. Use instead "high-tension" and "low-tension."

[H. PENDER.]

ACIDS.—The properties of some of the more important acids used in the arts are given in the following paragraphs.

Aqua Regia is a mixture of one part of nitric acid and three parts of hydrochloric acid. It obtains its name from the fact that it will dissolve gold. It is used as an oxidizing agent and for dissolving metals, such as platinum, gold, etc., which are insoluble in other acids. It should be used as soon as possible after being prepared since it loses its characteristic properties after standing a short time. It is distinguished by its reddish yellow color and its chlorine-like odor.

Hydrochloric Acid or Muriatic Acid (HCl) is an aqueous solution of hydrogen chloride, a colorless, pungent gas. While the pure acid is colorless, the commercial acid is a yellowish liquid, the color being due to impurities. The concentrated acid has a specific gravity of 1.16 and contains 32 per cent of HCl. The dilute acid has a specific gravity of 1.09 and contains 18.4 per cent of HCl. Hydrochloric acid is used extensively in the manufacture of chlorine, hydrogen and bleaching powder and is prepared as a by-product of the soda manufacture. The acid is recognized by its odor and by the dense fumes it makes with ammonia.

Hydrofluoric Acid (HF) is an aqueous solution of anhydrous hydrogen fluoride, a colorless, fuming liquid. The acid, when saturated, has a specific gravity of 1.25. Its gas is poisonous if inhaled and causes swellings and pain if applied to the skin. It readily dissolves glass and must be kept in platinum, lead, rubber or wax vessels. The acid is most commonly used for etching glass.

Nitric Acid (HNO_3) is a colorless fuming liquid with a specific gravity of 1.55 at 0° C. Commercial nitric acid has a specific gravity of 1.414 at 15° C. and contains 68 per cent of the pure acid. The commercial acid is yellowish in color and the pure acid becomes yellow if exposed to the light. Nitric acid is a powerful oxidizing agent and decomposes organic substances. The acid is used in the manufacture of many chemical substances. Concentrated nitric acid is best recognized by the red fumes, which are given off when the acid is acting upon a metal.

Sulphuric Acid or Oil of Vitriol (H_2SO_4) is a colorless oily liquid. The concentrated acid has a specific gravity of 1.854 at 0° C. and contains 1.5 per cent of water. Commercial sulphuric acid, sometimes known as "brown acid," has a specific gravity of 1.720 and usually contains arsenic as an impurity. Sulphuric acid boils at 290° C., the temperature increasing to 338° C. as the boiling continues. The acid has a strong affinity for water and is frequently used as a drying agent. When diluted with water, the mixing should be performed gradually as great heat is evolved. The acid should be added to the water as the addition of water to the acid may produce violent explosions due to the ebullition of the water.

Sulphuric acid is used in the manufacture of many chemical substances, in dyeing and in refining petroleum. It is a fairly good conductor of electricity and is used in the lead type of storage batteries (q.v.). The acid is recognized by its weight, by its carbonizing action upon organic bodies and by the white precipitate formed by the addition of barium chloride.

[R. G. Hudson.]

ALLOYS.—In this article is given a brief description of some of the more common alloys used in engineering work, together with specific data on some of their more important properties. It should be noted that there may be a considerable departure from the quantitative values given. Traces are not included in the chemical compositions given. The various alloys are listed alphabetically. Additional data on their various physical properties will be found in the articles on *Heat and Thermal Properties; Resistance and Conductance; Strength and Elasticity; Weight of Materials; Wires, Resistor; etc.*

Aluminum Brass (70.5 Cu, 26.4 Zn, 3.1 Al).—The tensile strength is about 21 tons per square inch, the elastic limit 8.5 tons per square inch and the elongation 50 per cent. Aluminum brass is used when very accurate castings are desired, e.g., for pumps, valves, pinions and propellers. It can be rolled and forged while hot but is not easily worked when the aluminum content exceeds 4 per cent.

Aluminum Bronze (95 Cu, 5 Al).—The tensile strength is about 28 tons per square inch, the elastic limit 12 tons per square inch and the elongation 75 per cent. Aluminum bronze containing less than 7.5 per cent Al is very ductile. With more than 7.5 per cent Al the alloy becomes brittle but increases in tensile strength. Tubes, propellers and propeller shafts are sometimes made of aluminum bronze. It has not been found to withstand intense heat for any length of time without fracturing. It is sometimes drawn into wire for use as an electrical resistance.

Amalgams are alloys of mercury and other metals. When newly made amalgams are plastic but harden in a short time without appreciable expansion or contraction. The common metals combined with mercury to form amalgams are tin, copper, cadmium, bismuth, silver and gold. Amalgams are used for silvering glass and as a cement for metals and porcelain.

Anti-friction Metals are alloys of copper, tin, zinc, lead and antimony in various combinations. These alloys are commonly used in bearings for revolving shafts and for valve packings. See *Babbitt and Bearing Metals* below.

Babbitt Metal (4 Cu, 69 Zn, 19 Sn, 5 Pb, 3 Sb) is used extensively for bearings, the composition stated being that used for car bearings of the Pennsylvania Railroad.

Bearing Metals for use in specific cases are illustrated by the following examples: Locomotive (82 Cu, 8 Zn, 10 Sn), railway car (90 Cu, 10 Sn), low-speed bearing (16 Sn, 84 Pb). There are a large number of anti-friction metals in use, the object in the composition of each of them being to procure a metal which is as hard as possible but plastic enough to be moulded by the shaft into a shape offering a minimum friction.

Brass is an alloy of copper and zinc and often contains small percentages of lead, tin, arsenic, antimony, bismuth and iron. *Cast brass* usually consists of 66 per cent of copper and 34 per cent of zinc. *Low brasses*, suitable for hot rolling, contain from 55 per cent to 63 per cent of copper. *High brasses*, suitable for cold rolling and drawing, contain from 60 per cent to 70 per cent of copper. In drawing brass it must be annealed and cleaned in acid at frequent intervals to prevent fracture. The ductility of brass is impaired if the lead content exceeds 0.1 per cent, but in the case of brasses intended for turning about 2 per cent of lead is often added so that the brass may be turned at higher speed and possess a better finish. Brass is made harder by the addition of about 1 per cent of tin and is found to better withstand corrosion due to salt water. The presence of small quantities of arsenic, antimony or bismuth in brass is liable to cause it to crack when rolled. The addition of 1 per cent to 3 per cent of iron to brass produces a harder and stronger alloy. The tensile strength of commercial

brass ranges from 15 to 40 tons per square inch and the elongation varies from 10 per cent to 40 per cent depending upon the composition.

Fusible (Low Melting Point) Metals consist of various alloys of bismuth, lead, tin and cadmium. The chemical composition of the common fusible metals and their melting points are given in the following table:

Alloy	Composition				Melting point °C.
	Bi	Pb	Sn	Cd	
Newton's alloy	50.0	31.25	18.75	.....	95
Rose's alloy	50.0	26.00	24.00	.....	100
Darcet's alloy	50.0	25.00	25.00	.....	93
Wood's alloy	50.0	24.00	14.00	12.00	66–71
Lipowitz' alloy	50.0	27.00	13.00	10.00	60

Lower melting points are obtained by the addition of mercury.

German Silver is an alloy of copper, nickel and zinc in various combinations. It is sometimes called nickel silver, argentan, packfong, silveroid, silverite or electrum. German silver is extensively used because of its ductility; it can be readily rolled, hammered and drawn. It is hard, tough and not easily corroded. Its composition varies from (50 Cu, 30 Ni, 20 Zn) to (57 Cu, 7 Ni, 36 Zn), the nickel content decreasing as the zinc increases. The usual impurities found in German silver are iron, lead and tin. The presence of iron in the alloy makes it stronger, harder and more elastic. Tin makes the alloy brittle. Lead is sometimes added to render the alloy more workable but should not be added when the alloy is to be rolled. German silver is drawn into wires for use as an electrical resistance and has been drawn into tubes for use in locomotive boilers. See *Wires, Resistor*.

Gun Metal is a bronze consisting of about 90 per cent of copper and 10 per cent of tin. The tensile strength varies from 12 to 16 tons per square inch, depending upon the method of working. It is mechanically strong and elastic and withstands severe shocks without fracture. If a small amount of lead is added to gun metal, the alloy is more easily turned or filed. Better castings are made by the addition of a small amount of zinc and the alloy is made harder by adding a small percentage of iron.

Manganese Bronze is an alloy containing copper, tin, zinc, lead, iron and manganese in various combinations. Alloys containing from 4 per cent to 6 per cent of manganese possess high tensile strength at high temperatures and are therefore used for fire-box stays. High tensile strength at ordinary temperatures is obtained, however, by the addition of very small quantities of manganese. The composition of manganese bronze for certain specific uses is as follows: For hydraulic machinery (82 Cu, 8 Sn, 5 Zn, 3 Pb, 2 Mn); for forging (58.6 Cu, 38.4 Zn, 1.6 Fe, 0.02 Mn). The tensile strength ranges from 27 to 38 tons per square inch but if the alloy is cold-rolled, a tensile strength of 50 tons per square inch may be obtained. Manganese bronze is often used in place of brass or copper, when a higher tensile strength is required. It is not easily corroded and may be bent when hot or cold.

Non-expansive Alloys are composed of iron, nickel and carbon. *Platinite* contains 46 per cent of nickel and 0.15 per cent of carbon. *Invar* contains 36 per

from 8×10^{-7} to 25×10^{-7} per degree centigrade. These alloys are used extensively in scientific instruments for standard measures of length and in incandescent lamps where the wire connections fused into the glass must not expand enough to fracture the glass.

Phosphor Bronze consists of copper, tin and phosphorus in various proportions, the phosphorus content rarely exceeding 2 per cent. The most useful property of phosphor bronze is its hardness and resistance to wear. Phosphor bronzes containing (A) 8 to 10 per cent of tin and 0.5 to 0.7 per cent of phosphorus are used for valves, pumps, propellers and boiler fittings, (B) 10 to 12 per cent of tin and 0.7 to 1 per cent of phosphorus are used for worms and gears and (C) 10 to 12 per cent of tin and 1 to 1.5 per cent of phosphorus are used for worms, gears and bearings where the wear is excessive. The tensile strength ranges from 10 to 15 tons per square inch, the elastic limit from 5 to 7 tons per square inch and the percentage elongation from 2 to 6 per cent.

Resistance Alloys. — See article on *Wires, Resistor*.

Solder is an alloy of tin and lead. *Hard* or tin solder contains 50 per cent of tin and 50 per cent of lead and melts at 370° F. *Soft* or plumber's solder contains 33.3 per cent of tin and 66.6 per cent of lead and melts at 441° F.

ALTERNATING CURRENTS. — (*See also Electricity and Magnetism, Principles of; Generators, Alternating-current; Motors, Alternating-current; Resistance and Conductance, Electric; Skin Effect; Transformers; Wave Analysis, etc.*). The following is a brief table of contents giving the main divisions of this article:

GENERAL DEFINITIONS. — (*See also Standardization Rules of the A.I.E.E.*). To avoid repetition the following definitions are given in terms of electric current; they also apply to electromotive forces, potential differences or to any other functions of time.

An alternating current is defined as a current which varies continuously with time from a constant maximum value in one direction to an equal maximum value in the opposite direction and back again to the same maximum in the first direction, repeating this cycle of values over and over again in *equal* intervals of time.

Period, Frequency and Alternations. — The period of an alternating current is the time taken for the current to pass through a complete cycle of positive and negative values.

The frequency or number of cycles per second is the number of periods per second.

The number of alternations per minute is the total number of times per minute that the current changes in direction, from positive to negative and from negative to positive. In engineering practice the number of cycles is usually referred to the second as the unit of time and the number of alternations is referred to the minute as the unit of time.

Let T be the period, f the frequency or number of cycles per second and a the number of alternations per minute, then

$$f = \frac{1}{T} \qquad \text{and} \qquad a = 120f = \frac{120}{T}. \tag{1}$$

The constant

$$\omega = 2\pi f = \frac{2\pi}{T} \tag{1a}$$

is sometimes called the angular velocity or angular frequency of the current. The name periodicity for this quantity is not recommended.

Instantaneous, Maximum and Average Values. — The instantaneous value of an alternating current is the value of the current at any instant. Instantaneous values of current, potential difference and electromotive force will be designated by small letters throughout this article, viz., i, v and e.

The maximum value of an alternating current is the numerical value of its maximum instantaneous value. Maximum values will be designated by capital letters with the subscript "m."

The average value of an alternating current for which the positive and negative half cycles are equal, which is usually the case, is defined as the numerical value of the average of its instantaneous values for a half cycle; the average over a complete cycle is of course zero. The general expression for the average value of a symmetrical current wave over a half cycle is

$$I_{\text{aver.}} = \frac{2}{T}\int_{t_0}^{t_0+\frac{1}{2}T} i\,dt, \tag{2}$$

Effective or R.M.S. Values. — The square root of the mean of the squares of the instantaneous values of an alternating current over a complete period is called the effective or r.m.s. value of the alternating current. In specifying the value of an alternating current as so many amperes this effective value is always meant unless specifically stated otherwise. In the same manner the square root of the mean of the squares of the instantaneous values of an alternating potential difference over a complete period is called the effective value of the alternating potential difference. When the value of an alternating potential difference is specified as so many volts, this effective value is always meant unless specifically stated otherwise.

The reason for selecting this particular function of the instantaneous values of an alternating current or potential difference as the measure of the current or potential difference is that the deflection of all instruments used in alternating-current measurements is a function of this effective value. See *Ammeters*, *Electrodynamometers*, *Voltmeters*, *etc.* Moreover, the average power dissipated as heat in a resistance r, when an alternating current of effective value I flows through it, is rI^2.

Effective values will be designated throughout this article by capital letters without subscripts.

The general expression for the effective value of an alternating current is

$$I = \sqrt{\frac{1}{T}\int_0^T i^2\,dt}, \tag{3}$$

and similarly for an alternating potential difference.

Form Factor. — The form factor of an alternating current is defined as the ratio of its effective to its average value, viz.,

$$\text{Form factor} = \frac{I}{I_{\text{aver.}}}, \tag{4}$$

and similarly for an alternating potential difference.

Crest or Peak Factor. — The crest factor, also called the peak factor or amplitude factor, of an alternating current is defined as the ratio of its maximum to its effective value, viz.,

$$\text{Crest factor} = \frac{I_{m.}}{I}. \tag{5}$$

Instantaneous and Average Power. — Let v be the value at any instant of the potential drop from any point 1 to any other point 2, and let i be the instantaneous value of the current from 1 to 2 at this same instant; then the power input at this instant is

$$p = vi. \tag{6}$$

When v and i are *both* positive (i.e., in the direction from 1 to 2, say) or when they are *both* negative, the power input is positive, but when v is positive and i negative or vice versa, the power input is negative, i.e., there is an actual power output.

The average value of the product vi over a complete period for both v and i (or over any whole number of periods) is the average power input or output, usually called simply the power input or output (input when the average of vi is positive, output when the average of vi is negative), the word average being understood. That is, the average power input is

$$P = \frac{1}{T}\int_0^T p\,dt = \frac{1}{T}\int_0^T vi\,dt, \tag{7}$$

T being a complete period. For the actual measurement of alternating-current power see *Wattmeters*.

Power Factor.— Only in certain special cases (*see below*) is the average power input P equal to the product of the effective value V of the potential difference by the effective value I of the current; it can never be greater and as a rule is less. The ratio of the average power P to the product of the effective value V of the potential difference by the effective value I of the current is called the power factor of the circuit between the terminals considered, i.e.,

$$\text{Power factor} = \frac{P}{VI}. \tag{8}$$

When V is expressed in volts and I in amperes then P must be in watts; when V is expressed in kilovolts and I in amperes P must be in kilowatts.

Volt-Amperes, Kilovolt-Amperes (kv-a.) — The product of the effective volts across the terminals of a circuit by the effective amperes through it is called the volt-amperes taken by the circuit; this product divided by 1000 is called the kilovolt-ampere input. Or, when V is in volts and I in amperes

$$\text{volt-amperes} = VI, \tag{9}$$

$$\text{kilovolt-amperes} = \frac{VI}{1000}. \tag{9a}$$

Kilovolt-amperes are usually abbreviated kv-a. or K.V.A., the former abbreviation being that recommended by the American Institute of Electrical Engineers and used in this book.

Effective Resistance (r) **and Conductance** (g). — The effective resistance of any portion of a circuit to an alternating current is the quotient of the average rate P_h at which heat is developed by this current, either directly in the substance through which it passes or indirectly as a consequence of the hysteresis and eddy-current losses produced by its magnetic field (*see Magnetic Properties of Iron*), divided by the square of the effective value I of the total current (conduction plus displacement or charging current) through this portion of the circuit, viz.,

$$r = \frac{P_h}{I^2}. \tag{10}$$

Similarly, calling V the effective value of the potential difference across the given portion of the circuit the effective conductance g of this portion of the circuit is defined by the relation

$$g = \frac{P_h}{V^2}. \tag{11}$$

In general, both r and g depend upon both the frequency and the wave-shape (*see below*) of the current and voltage but in many instances they may be considered as practically constant irrespective of the frequency or wave-shape. See the articles on *Resistance and Conductance* and *Skin Effect* for further discussion.

Impedance (z) **and Admittance** (y). — Let V be the effective value of the potential drop through any portion of a circuit due to its effective resistance, self-inductance and capacity (*see Electricity and Magnetism, Principles of*), i.e., if there is any other source of e.m.f. in the given portion of circuit (e.g. a generator or motor) V is the effective potential drop which the same current would produce through this portion of circuit were this external source of e.m.f. removed. Then the quotient of the potential drop V by the current I in this portion of the circuit, viz.,

$$z = \frac{V}{I}, \tag{12}$$

is defined as the impedance of this portion of the circuit.

The reciprocal of the impedance, viz.,

$$y = \frac{1}{z} = \frac{I}{V}, \tag{13}$$

is defined as the admittance of the given portion of the circuit.

Impedance and admittance, as thus defined, both depend upon the frequency and wave-shape. Impedance is expressed in the same units as resistance (e.g. ohms), and admittance in the same units as conductance (e.g. mhos); see *Units and Conversion Factors*.

Reactance (x) and Susceptance (b). — The square root of the difference between the square of the impedance and the square of the effective resistance of a given portion of an electric circuit is defined as the reactance x of this portion of the circuit, viz.,

$$x = \sqrt{z^2 - r^2}. \tag{14}$$

The reactance of a coil of inductance L to a sine-wave current of frequency f is

$$x = 2\pi f L. \tag{14a}$$

Similarly, the susceptance b of the given portion of the circuit is defined by the relation

$$b = \sqrt{y^2 - g^2}. \tag{15}$$

The susceptance of a condenser of capacity C to a sine-wave voltage of frequency f is

$$b = 2\pi f C. \tag{15a}$$

The simple relations expressed by (14a) and (15a) hold only for *sine-wave* currents and voltages; see Pender, H., *Principles of Electrical Engineering*, N. Y., 1912. See also the articles in this book on *Capacity and Charging Current* and *Inductance and Inductive Reactance*.

Inductive and Condensive (or Capacity) Reactance and Susceptance. — The reactance of a circuit may be due either to the back e.m.f. set up as a consequence of the varying magnetic field of the current or to a back e.m.f. set up by a condenser or its equivalent, or to both. In the first case the reactance and susceptance are said to be "inductive" and in the second case "condensive." A condensive reactance or susceptance is equivalent to a *negative* inductive reactance or susceptance; e.g., the inductive susceptance of a condenser to a sine-wave voltage is $-2\pi f C$.

Equivalent* Resistance, Impedance and Reactance. — Sometimes in calculating alternating-current circuits it is convenient to consider a motor or other load developing a back e.m.f. as equivalent to a single resistance and reactance. Let P be the total power taken by the load, V the voltage between its terminals, I the current; then the equivalent resistance is defined as

$$R = \frac{P}{I^2}, \tag{16}$$

the equivalent impedance as

$$Z = \frac{V}{I} \tag{16a}$$

and the equivalent reactance as

$$X = \sqrt{Z^2 - R^2}. \tag{16b}$$

The difference between the *effective* resistance and the *equivalent** resistance is

* The distinction here made between equivalent and effective is not always observed; the term equivalent resistance is frequently used in the same sense as effective resistance.

that the first takes into account only the power dissipated as heat, whereas the latter takes into account the total power, of which only a part is heat, the rest being converted into some other form, e.g. mechanical power.

SIMPLE HARMONIC OR SINE-WAVE CURRENTS AND VOLTAGES. — A simple harmonic or sine-wave current is one which varies with time according to the sine formula

$$i = I_m \sin(\omega t + \theta),$$

where t represents time in seconds, measured from any arbitrarily chosen instant, I_m the maximum value of the current, $\omega = 2\pi f = \frac{2\pi}{T}$, where f is the frequency in cycles per second and T the period as a fraction of a second, and θ a constant, called the "phase angle," which depends upon the instant chosen as the zero of time. See the section on *Harmonic Motion* in the article on *Mechanics, Principles of,* for a full discussion of this equation and its physical significance.

Difference in Phase Between a Sine-wave Current and a Sine-wave Voltage of the Same Frequency. — In general, when a sine-wave electromotive force is impressed on a circuit the resulting current is likewise a sine function of time (after a very brief interval, see *Transient Electric Phenomena and Oscillations*) having the same frequency, but the e.m.f. and current do not reach their maximum values simultaneously. Let the current and the potential drop in the direction of the current be represented respectively by the two equations

$$i = I_m \sin \omega t,$$
$$v = V_m \sin(\omega t + \theta),$$

where t is the time measured from the instant when $i = 0$ and is increasing in the *positive* direction. The current reaches its maximum value when $t = \frac{\pi}{2\omega}$, while the potential drop reaches its maximum value when $t = \frac{\pi}{2\omega} - \frac{\theta}{\omega}$. Hence when θ is positive the potential drop reaches its maximum value $\frac{\theta}{\omega}$ seconds *before* the current reaches its maximum, or the current reaches its maximum value $\frac{\theta}{\omega}$ seconds *after* the potential drop reaches its maximum; when θ is negative the current reaches its maximum value $\frac{\theta}{\omega}$ seconds *before* the potential drop reaches its maximum. In the first case the current is said to "lag behind" the potential drop, and in the second case the current is said to "lead" the potential drop. The angle θ is called the "difference in phase," or simply the phase angle, between the current and potential drop.

In general, when i and v are expressed by the formulas

$$i = I_m \sin(\omega t + \theta_i),$$
$$v = V_m \sin(\omega t + \theta_v),$$

i reaches its first maximum at an interval of time $\frac{1}{\omega}(\theta_i - \theta_v)$ ahead of v, and therefore i leads v by the angle $\theta_i - \theta_v$. Note the order of the subscripts: *i leads v* by the angle $\theta_i - \theta_v$; or *v leads i* by $\theta_v - \theta_i$. A negative lead is of course equivalent to an actual lag, and a negative lag is equivalent to an actual lead.

Currents and Voltages in Phase, in Quadrature and in Opposition. — When the phase difference is zero the current and potential drop are said to be "in phase"; when the phase difference is $\frac{\pi}{2}$ radians or 90° the current and potential drop are said to be "in quadrature"; when the phase difference is π radians or 180° the current and potential drop are said to be "in opposition."

Effective and Average Values, Form Factor and Crest Factor of Sine-wave Currents and Voltages. — When the current and voltage vary according to the sine law, as explained above, the following relations hold:

$$\text{Effective value} = \frac{\text{Maximum value}}{\sqrt{2}}; \qquad (17)$$

$$\text{Average value} = \frac{2}{\pi} \times (\text{maximum value}); \qquad (17a)$$

$$\text{Form factor} = \frac{\pi}{2\sqrt{2}} = 1.11; \qquad (17b)$$

$$\text{Crest factor} = \sqrt{2} = 1.414. \qquad (17c)$$

For any other relation between the instantaneous values of the current or voltage and time, i.e., for any other shape of current or voltage wave, *these relations do not hold;* see definitions above and article on *Wave Analysis.*

Power and Power Factor for Sine-wave Current and Voltage. — Let the voltage drop from terminal No. 1 to terminal No. 2 through any piece of apparatus be $v = \sqrt{2}\,V \sin(\omega t + \theta_v)$ and the current from terminal No. 1 to terminal No. 2 be $i = \sqrt{2}\,I \sin(\omega t + \theta_i)$, where V and I are the effective values and therefore $\sqrt{2}\,V$ and $\sqrt{2}\,I$ are the maximum values. Then the *instantaneous* power input is

$$p = vi = VI\,[\cos(\theta_v - \theta_i) - \cos(2\,\omega t + \theta_v + \theta_i)]. \qquad (18)$$

A study of Fig. 1 will show the physical meaning of this expression. The *average* power input is

$$P = VI \cos(\theta_v - \theta_i), \qquad (18a)$$

where $(\theta_v - \theta_i)$ is the difference in phase between the current and voltage. Putting θ for this difference in phase, viz., $\theta = \theta_v - \theta_i$, equation (18a) may be written

$$P = VI \cos\theta. \qquad (18b)$$

Whence the power factor of the load supplied to the apparatus is, from equation (8),

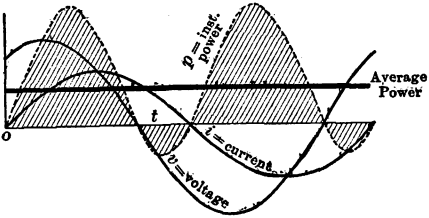

Fig. 1.

$$\cos\theta = \frac{P}{VI}. \qquad (19)$$

Power-factor Angle. — Since in the case of sine-wave currents and voltages the power factor is equal to the cosine of the angle which expreses the difference in phase between them, this difference in phase is frequently called the "power-factor angle." When the wave shape is not a pure sine

curve, the power factor cannot be interpreted as the cosine of the phase difference, for phase difference has no definite meaning except in reference to sine waves; see definitions above. A non-sinusoidal voltage and current may both reach their zero values at the same instant, as in the case of an arc (*see Arc, Electric*), and in a sense may be said to be "in phase," but the power factor as defined by equation (8) may be far from unity.

Leading and Lagging Power Factor. — The power factor is always a positive quantity, but the power-factor angle may be either positive or negative, i.e., the current may lag behind or lead the voltage drop by any angle between 0° and 90°, or lag behind or lead the potential drop by any angle between 0° and 90°.* When the current lags behind the reference voltage by an angle between 0° and 90° the power factor is stated as such a fraction or percentage, *lagging*, e.g., a power factor of 80% lagging, and when the current leads the power factor is stated as such a fraction or per cent, *leading*. In the first case the power-factor angle is taken as positive, and in the second case negative.

Equivalent Sine-wave Currents and Voltages. — In very few instances are the actual currents and voltages in a circuit pure sine-waves, but many of the ordinary calculations of alternating-current circuits may be made with sufficient accuracy by assuming them as sine-waves of the same *effective* values as the actual waves, and differing in phase by the angle whose cosine is equal to the actual power factor, i.e., by the angle

$$\theta = \cos^{-1}\frac{P}{VI}, \tag{19a}$$

where P is the average power, V the effective value of the actual voltage and I the effective value of the actual current.

Vector Representation of Sine-wave Currents and Voltages. — Consider any sine function

$$i = I_m \sin \omega t.$$

The value of i at any instant may be represented graphically, see Fig. 2, by the vertical projection (i.e., the vertical distance from P_1 to OX) of a point P_1 at the end of a radius $OP_1 = I_m$ which revolves† at an angular speed ω about a fixed point O, the angle ωt being measured from the horizontal fixed line OX. Similarly, any other sine function

$$v = V_m \sin(\omega t + \theta)$$

may be represented by the vertical projection of the point P_2 at the end of a radius $OP_2 = V_m$ also revolving about O with an angular speed ω, the angle between OP_1 and OP_2, *when the frequency of both i and*

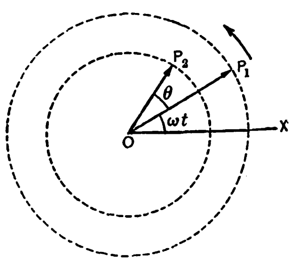

Fig. 2.

* When there is an actual power input into a portion of a circuit (e.g., a motor) it is most convenient to refer the current to the voltage *drop* through this portion of circuit in the direction of the current; when there is an actual power output (e.g., a generator) it is most convenient to refer the current to the voltage *rise* through this portion of the circuit, i.e., to the electromotive force in this portion of the circuit, in the direction of the current. When the potential *rise* is used as the reference, then for a power-factor angle between − 90° and 0° and between 0° and + 90°, the apparatus gives out power, and for a power-factor angle between − 90° and − 180° and between + 90° and + 180° the apparatus absorbs power.

† Counter-clockwise rotation has been adopted (1911) as standard by the International Electrotechnical Commission.

v is the same, remaining fixed in value and equal to the difference in phase θ between v and i. That is, v and i may be represented by rotating vectors (*see article on Vectors*) and when of the same frequency the relative position of the two vectors remains fixed. Similarly any number of currents and voltages of the same frequency may be represented by rotating vectors which remain fixed with respect to one another.

Instead of referring the various rotating vectors to a *fixcd* line OX, this line of reference may also be considered as rotating with the same speed ω as the various vectors, or any one of the vectors may be chosen as the line of reference, for example, the vector OP_1 in Fig. 2. The rotating vectors referred to this rotating line of reference are then fixed with respect to this line of reference, and the entire diagram may be considered as fixed, as in Fig. 3, the originally chosen fixed line of reference OX rotating in the opposite direction with an angular speed ω.

Instead of making the vectors equal in length to the maximum values of the sine functions they may be chosen equal in length to their *effective* values. This merely introduces a factor $\sqrt{2}$, so that when any vector is considered as rotating the instantaneous value of the quantity which it represents is equal to $\sqrt{2}$ times the perpendicular distance from its end to the fixed line of reference.

Addition of Sine-wave Currents or of Sine-wave Voltages. — Since the effective values and phase relations of sine-wave currents and voltages may be represented by vectors, sine-wave currents are added in exactly the same manner as vectors, or forces, are added, and similarly for sine-wave voltages. The addition of vectors is fully treated in the article on *Vectors*, q.v. To add any two sine-wave currents or voltages not only must their effective values be known but also their phase relation; *the resultant of two alternating voltages of effective values V_1 and V_2 is never the arithmetical sum of V_1 and V_2,* except when the two voltages are exactly in phase, and similarly for alternating currents.

In-phase and Quadrature Components. — In Fig. 3, considering OP_1 as equal to the effective value I of the current and OP_2 as representing the effective value V of the voltage, the voltage V may be considered as made up of two components, viz.:

$V_1 = V \cos\theta$ in phase with I,

$V_2 = V \sin\theta$ in quadrature with I.

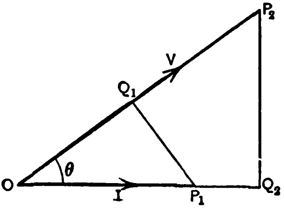

Fig. 3.

The average power corresponding to the component $V_1 = V \cos\theta$ is, from equation (18b), $IV_1 = IV \cos\theta$, and is equal to the total power corresponding to V and I. The average power corresponding to the component $V_2 = V \sin\theta$, since the angle between the current and this component of the voltage is 90°, is equal to zero. The voltage component $V_1 = V \cos\theta$ is therefore frequently called the "power" component of the voltage, and the component $V_2 = V \sin\theta$ is frequently called the "wattless" component of the voltage. These terms, however, are not recommended. It is preferable to refer to these two components as the in-phase and quadrature components respectively. The terms active and reactive components are also used.

Similarly, the current I may be considered as made up of two components, viz.:

$I_1 = I \cos\theta$ in phase with V,

$I_2 = I \sin\theta$ in quadrature with V.

The first component is called the in-phase component of the current and the second the quadrature component of the current.

Resistance Drop and Reactance Drop. — When a sine-wave current of effective value I is established in a coil which has an effective* resistance r and inductance L, the drop of voltage V through the coil is represented by the vector diagram shown in Fig. 4. The reactance of such a coil, from the definition given by equation (14a), is then $x = 2\pi fL$. The voltage drop rI, due to the resistance of the coil, is in phase with the current I, whereas the voltage drop $2\pi fLI = xI$, due to the reactance of the coil, is 90° ahead of the current. A "resistance drop" i.e., the drop of potential due to a current through a resistance, is always in phase with the current which causes it, and an *inductive* reactance drop is always 90° ahead of the current which produces it. (A *condensive* reactive drop is always 90° behind the current which causes it, and is therefore directly opposite in phase to an inductive reactance drop produced by the same current.)

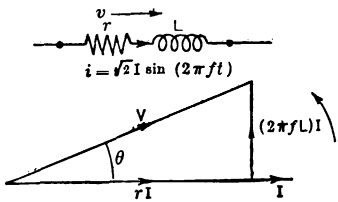

Fig. 4.

Impedance of a Coil to a Sine-wave Current. — From Fig. 4 and the definition of impedance, equation (12), it is evident that the impedance of a coil of resistance r and inductance L is

$$z = \sqrt{r^2 + (2\pi fL)^2}. \tag{20}$$

Leakage Current and Charging Current of a Condenser. — When a sine-wave voltage of effective value V is established across a condenser which has an effective† conductance g and capacity C, the total current I through it is represented by the vector diagram shown in Fig. 5. The *condensive* susceptance of a condenser from the definition given in equation (15a) is then $b = 2\pi fC$, or the *inductive* susceptance is $b' = -b = -2\pi fC$. The conduction or leakage current gV is in phase with the voltage drop through the condenser, whereas the charging or capacity current (or displacement current) $2\pi fCV = bV$ is 90° ahead of the voltage.

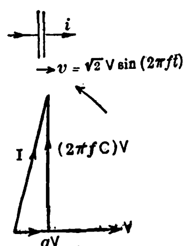

Fig. 5.

Admittance, Impedance, Effective Resistance and Reactance of a Condenser. — From Fig. 5 and the definitions given by equations (12) to (15) it follows that the admittance of a condenser to a sine-wave voltage is

$$y = \sqrt{g^2 + (2\pi fC)^2}; \tag{21}$$

the impedance is

$$z = \frac{1}{y} = \frac{1}{\sqrt{g^2 + (2\pi fC)^2}}; \tag{21a}$$

* When the coil has a non-magnetic core and the frequency is low, say 60 cycles or less, the effective resistance is practically equal to its ohmic or d-c. resistance; see article on *Skin Effect.*

† Even for moderate frequencies, 25 cycles or more, the effective conductance of a condenser is in general many times its ohmic conductance; see article on *Condensers, Electric.*

the effective resistance is

$$r = \frac{g}{g^2 + (2\pi fC)^2}; \tag{21b}$$

and the effective *condensive* reactance is

$$x_C = \frac{2\pi fC}{g^2 + (2\pi fC)^2}, \tag{21c}$$

which is equivalent to an *inductive* reactance of

$$x = -x_C = \frac{-2\pi fC}{g^2 + (2\pi fC)^2}. \tag{21d}$$

Only when the effective conductance g is zero is the reactance of a condenser equal to $-\frac{1}{2\pi fC}$, but in many instances the value of g is so small compared with $2\pi fC$ that the inductive reactance may be taken as $-\frac{1}{2\pi fC}$; the error in this approximate expression is less than 1 per cent for g less than 10 per cent of $2\pi fC$.

Relations between Effective Resistance, Reactance and Impedance and Effective Conductance, Susceptance and Admittance for Sine-wave Currents and Voltages. — From the definitions given above, equations (12) to (15), it may be shown that for sine-wave currents and voltages of a given frequency the following relations hold for any portion of a circuit:

$$\left.\begin{array}{ll} z = \sqrt{r^2 + x^2}, & y = \sqrt{g^2 + b^2}, \\ z = \dfrac{1}{y}, & y = \dfrac{1}{z}, \\ r = \dfrac{g}{y^2}, & g = \dfrac{r}{z^2}, \\ x = \dfrac{b}{y^2}, & b = \dfrac{x}{z^2}, \end{array}\right\} \tag{22}$$

where r = effective resistance, x = reactance (taken positive when inductive), z = impedance, g = effective conductance, b = susceptance (taken positive when inductive) and y = admittance, all for the given portion of circuit. Equations (20) to (21d) are special cases of equation (22).

Impedances in Series. — Let z_1, z_2, z_3, etc., be the impedances of the several portions of a circuit all connected in series (same current through each). Then the resultant impedance is

$$\left.\begin{array}{ll} & Z = \sqrt{R^2 + X^2}, \\ \text{where} & R = r_1 + r_2 + r_3 + \text{etc.}, \\ \text{and} & X = x_1 + x_2 + x_3 + \text{etc.}, \end{array}\right\} \tag{23}$$

where r_1, r_2, r_3, etc., are the effective resistances and x_1, x_2, x_3, etc., the reactances (condensive reactances to be considered as negative) of the several impedances. When there is no external source of e.m.f. in any portion of the circuit, then the resultant power factor is $\cos\theta$ where

$$\tan\theta = \frac{x_1 + x_2 + x_3 + \text{etc.}}{r_1 + r_2 + r_3 + \text{etc.}}. \tag{23a}$$

Example. — An alternating current of 100 amperes is to be supplied to a receiver which has an equivalent resistance r_1 of 2 ohms and an equivalent

reactance x_1 of 0.5 ohm. The line has a resistance r_2 of 0.1 ohm and an inductive reactance x_2 of 1.5 ohms. The equivalent resistance of the line and receiver is then $R = 2 + 0.1 = 2.1$ ohms and the equivalent reactance of the line and receiver is $X = 0.5 + 1.5 = 2.0$ ohms. Hence the equivalent impedance of the line and receiver is $Z = \sqrt{(2.1)^2 + (2.0)^2} = 2.90$ ohms. The impedance of the receiver alone is $z_1 = \sqrt{(2)^2 + (0.5)^2} = 2.06$ ohms and the impedance of the line alone is $z_2 = \sqrt{(0.1)^2 + (1.5)^2} = 1.50$ ohms. The arithmetical sum of z_1 and z_2 is 3.56, which is 23 per cent greater than the true impedance of the line and receiver.

When the current supplied to the receiver is 100 amperes, the voltage at the receiver is $V = 100 \times z_1 = 100 \times 2.06 = 206$ volts and the voltage at the generator is $V_0 = 100 \times Z = 100 \times 2.90 = 290$ volts, see Fig. 6, that is, the voltage at the receiver is $290 - 206 = 84$ volts less than at the generator. The total potential drop in the two wires forming the line, however, is $100 \times z_2 = 100 \times 1.50 = 150$ volts, which is 79 per cent greater than the true difference between the potential drops across the generator and across the receiver terminals.

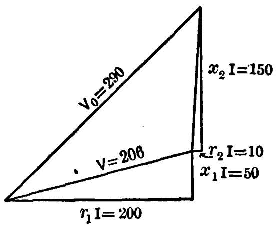

Fig. 6.

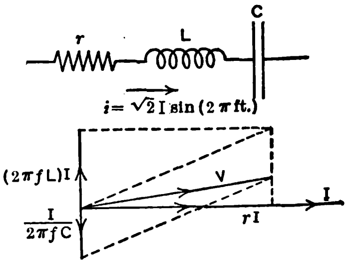

Fig. 7.

Resonance of a Coil and Condenser in Series.—Consider the circuit shown in Fig. 7. When a sine-wave current of effective value I is established in such a circuit the voltage drop across the resistance is $V_r = rI$ and is in phase with I. The voltage drop across the inductance is $V_L = (2\pi fL)\,I$ and *leads* I by 90.° The voltage drop across the capacity (a condenser with *negligible* conductance) is $V_c = \frac{I}{2\pi fC}$ and *lags behind* I by 90°. Hence the resultant voltage across the entire circuit is

$$V = \overline{V_r + V_L + V_C} = I\sqrt{r^2 + \left(2\pi fL - \frac{1}{2\pi fC}\right)^2}. \tag{24}$$

The reactance is therefore

$$x = \sqrt{z^2 - r^2} = \left(2\pi fL - \frac{1}{2\pi fC}\right).$$

When the inductance L, capacity C and frequency f are so related that

$$f = \frac{1}{2\pi\sqrt{LC}} \tag{25}$$

the reactance of the circuit is zero, the impedance is equal to the resistance, the power factor is unity and the current corresponding to a given voltage V is $I = \frac{V}{r}$; that is, the current is a maximum and depends only upon the resistance

of the circuit. The frequency corresponding to this condition is the same as the frequency with which the current and p.d. would oscillate were the condenser short-circuited by the inductance; i.e., this frequency corresponds* to the free period of such a circuit (*see Transient Electric Phenomena and Oscillations*). In general, a condenser and coil in series are said to be in resonance with the impressed frequency when the current for a given impressed voltage is a maximum, and the power factor therefore unity. When the conductance of the condenser is negligible the resonant frequency is given by equation (25).

When resonance obtains in a series circuit the voltage across the coil and that across the condenser may be many times the impressed voltage. For example, when the inductance L is 1 henry, the capacity C is 7.04 microfarads, and the frequency is 60 cycles, the inductive reactance is $x_L = 2\pi \times 60 \times 1 = 377$ ohms, the condensive reactance is $x_C = \dfrac{1}{2\pi \times 60 \times 7.04 \times 10^{-6}} = 377$ ohms, and the circuit is in resonance. For a resistance of 1 ohm in the coil and an impressed e.m.f. of 100 volts, the voltage across the coil is $\sqrt{(100)^2 + (377 \times 100)^2} = 37{,}700$ volts and the voltage across the condenser is $377 \times 100 = 37{,}700$ volts.

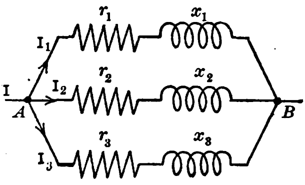

Fig. 8.

Impedances in Parallel.— Let z_1, z_2, z_3, etc., be the impedances of several branch circuits as shown in Fig. 8, and let the resistances and reactances constituting these impedances be r_1, r_2, r_3, etc., and x_1, x_2, x_3, etc., respectively.† First calculate the corresponding conductances g_1, g_2, g_3, etc., and susceptances b_1, b_2, b_3, etc., using equations (22). Then the resultant admittance, *provided there are no external sources of e.m.f. in any of the branches*, is

$$Y = \sqrt{G^2 + B^2},$$

where

$$\left.\begin{aligned} G &= g_1 + g_2 + g_3 + \text{etc.}, \\ B &= b_1 + b_2 + b_3 + \text{etc.}, \end{aligned}\right\} \qquad (26)$$

and the resultant power factor is $\cos\theta$ where

$$\tan\theta = \frac{b_1 + b_2 + b_3 + \text{etc.}}{g_1 + g_2 + g_3 + \text{etc.}}. \qquad (26a)$$

Resonance of a Coil and Condenser in Parallel. — When a coil of negligible resistance and a condenser of negligible conductance are connected in parallel, the resultant current established through the circuit by a given impressed voltage will be *zero* (infinite impedance) when the inductance L, capacity C and frequency f bear the following relation:

$$f = \frac{1}{2\pi\sqrt{LC}}. \qquad (27)$$

Compare with equation (25). Under these conditions the coil and condenser are said to be in resonance with the impressed frequency. When the coil has an appreciable resistance and the condenser an appreciable conductance they are said to be in resonance when the resultant current is a minimum for a given impressed voltage, and the power factor therefore unity.

* Approximately only when r is large; see *Transient Electric Phenomena and Oscillations*.

† Condensive reactances to be considered negative.

NON-SINUSOIDAL CURRENTS AND VOLTAGES. — The general expression for any alternating current, or in fact of any continuous periodic function, is

$$i = \sqrt{2}\, I_1 \sin(\omega t + \theta_1) + \sqrt{2}\, I_2 \sin(2\,\omega t + \theta_2) + \sqrt{2}\, I_3 \sin(3\,\omega t + \theta_3) + \ldots,$$

where I_1, I_2, I_3, etc., represent effective values of each of the terms. That is any current or voltage wave may be considered as made up of a "fundamental" sine-wave, having the same frequency as that of the actual wave, and "harmonic" sine-waves having frequencies which are integral multiples of the frequency of the fundamental. Alternating currents and voltages in practice usually contain one or more of the *odd* harmonics; *even* harmonics practically never occur in ordinary electric circuits supplied from commercial forms of generators. However, as noted above, it is permissible in most instances to assume sine-wave currents and voltages, since the harmonics present are usually relatively weak compared with the fundamental. In certain instances, however, it is necessary to analyze a wave into its fundamental and harmonics. For methods of experimentally determining the shape of current and voltage waves see the articles on *Oscillographs* and *Braun Tube;* for the analysis of the curves themselves see the article on *Wave Analysis*.

Effective Value of a Non-sinusoidal Wave. — The effective value of such a wave can be obtained directly from equation (3), or if the effective values I_1, I_2, I_3, etc., of the harmonic and fundamentals are known the effective value of the resultant wave is

$$I = \sqrt{I_1^2 + I_2^2 + I_3^2 + \ldots} \qquad (28)$$

A like relation holds for the effective value of a voltage wave. Similarly, if for example a 25-cycle e.m.f., say E_{25}, and a direct e.m.f., say E_d, are acting in series in the same circuit, the resultant e.m.f. of the combination is

$$E = \sqrt{E_{25}^2 + E_d^2}.$$

Power Corresponding to Non-sinusoidal Currents and Voltages. — Let I_1 be the effective value of the fundamental (first harmonic) of the current, V_1 the effective value of the fundamental of the voltage and θ_1 the difference in phase between these two fundamentals, both being of the same frequency; let I_2, V_2 and θ_2 be the corresponding quantities for the second harmonic; let I_3, V_3 and θ_3 be the corresponding values for the third harmonic, etc. Then the average power is

$$P = V_1 I_1 \cos\theta_1 + V_2 I_2 \cos\theta_2 + V_3 I_3 \cos\theta_3 + \text{etc.}$$

That is, each harmonic contributes an amount to the total power equal to the power it would develop were the other harmonics not present. If, for example, the third harmonic is not present in the current wave, then this harmonic contributes nothing to the average power even though there may be a large third harmonic in the voltage wave. Again, when a 25-cycle alternating electromotive force E_{25} and a direct electromotive force E_d are acting in series on the same circuit the power developed is the sum of the powers which each would develop if they acted separately, but the resultant e.m.f. of the combination is not $E_{25} + E_d$, but, as noted above, is $\sqrt{E_{25}^2 + E_d^2}$.

Calculation of Networks when the Currents and Voltages are Non-sinusoidal. — See below under *Symbolic Notation*, equations (31) and (32), and the accompanying text.

SYMBOLIC NOTATION FOR EXPRESSING SINE-WAVE CURRENTS AND VOLTAGES. — Since sine-wave currents and voltages may be represented by vectors equal in length to the effective values of these quan-

tities and making definite constant angles with one another, two mutually perpendicular axes of references may be chosen, and each current and voltage resolved into two components, one along the X-axis or horizontal axis and one along the Y-axis or vertical axis. The component along the X-axis may be expressed as an ordinary algebraic quantity, and the component along the Y-axis may also be expressed as an algebraic quantity with the symbol "j" written in front of it to indicate that it is perpendicular to the X-component, That is, any current may be written

$$\underset{\cdot}{I} = I_1 + jI_2,$$

where I_1 is the horizontal or X-component of the current and I_2 the vertical or Y-component. Until one gets familiar with this notation it is best to indicate the symbolic nature of the currents, voltages, impedances, etc., by writing dots under them; but these dots may be dispensed with in the actual solution of problems by this method when one keeps clearly in mind that in all operations the various quantities are to be treated as *complex* quantities throughout.

A voltage drop in symbolic notation is expressed in a similar manner, viz.,

$$\underset{\cdot}{V} = V_1 + jV_2,$$

and an electromotive force as

$$\underset{\cdot}{E} = E_1 + jE_2,$$

the *same* axis of reference being used for the currents, voltage drops and electromotive forces.

Impedance and Admittance in Symbolic Notation. — In this notation an impedance of resistance r and reactance* x is represented by the complex quantity

$$\underset{\cdot}{z} = r + jx, \tag{29}$$

and an admittance of conductance g and susceptance* b by the complex quantity

$$\underset{\cdot}{y} = g - jb. \tag{29a}$$

These expressions are independent of the axes of reference chosen.

Currents, Voltages, Impedances and Admittances as Complex Numbers. — In all operations involving the addition or subtraction of currents or voltages and in all operations involving products of currents and impedances or products of voltages and admittances, these quantities when written in symbolic notation may be treated as complex quantities (*see article on Complex Quantities*), *provided all the currents and voltages are referred to the same axis of references*. In all such operations the symbol "j" may be considered as mathematically equivalent to $\sqrt{-1}$. Hence when a term of the form $A_1 + jA_2$ occurs in the denominator of any fraction, the fraction may be "rationalized" by multiplying numerator and denominator by $A_1 - jA_2$, which gives

$$\frac{1}{A_1 + jA_2} = \frac{A_1 - jA_2}{A_1^2 + A_2^2}. \tag{30}$$

In any resulting expression for a current or voltage when thus rationalized the "real" part represents the actual component of the current or voltage in the direction of the X-axis and the "j" part, i.e., the sum of the terms which are multiplied by j, represents the actual component of the current or voltage along the Y-axis.

* Taken positive when inductive, negative when condensive, e.g., the admittance of a condenser is $g + j\,(2\pi fC)$.

Solution of Alternating-current Networks. — When all the currents, voltages, impedances and admittances are expressed in symbolic notation, the following relations hold:*

1. The sum of all the currents flowing to any point in any network of conductors is zero. That is, at any point

$$\dot{I} + \dot{I}' + \dot{I}'' + \ldots = 0, \tag{31}$$

where the currents are all expressed in symbolic notation and are all referred to the *same* line of reference.

2. The sum of all the impedance drops in a given direction around any closed loop in any network of conductors is equal to the sum of all the *externally induced e.m.f.'s* acting in this loop in this direction. That is, around any closed loop

$$\dot{z}\dot{I} + \dot{z}'\dot{I}' + \dot{z}''\dot{I}'' + \ldots = \dot{E} + \dot{E}' + \dot{E}'' + \ldots, \tag{32}$$

where the currents, impedances and electromotive forces are all expressed in symbolic notation, and the *currents and e.m.f.'s are all referred to the same axis of reference.* That is, the currents are to be expressed as $\dot{I} = I_1 + jI_2$, $\dot{I}' = I_1' + jI_2'$, etc., and the e.m.f.'s as $\dot{E} = E_1 + jE_2$, $\dot{E}' = E_1' + jE_2'$, etc., where all the components of the currents and e.m.f.'s with the subscript 1 are parallel to one another and all those with the subscript 2 are parallel to one another and lead the first set of components by 90 degrees.

The electromotive forces due to inductance and capacity are taken account of by the impedance; the electromotive forces represented by the E's in equation (32) are the externally induced electromotive forces such as those due to generators or motors or to the mutual inductance of the two windings of a transformer.

In applying equations (31) and (32) to the calculation of the currents and potential drops in any network of circuits, care must be taken to designate clearly the sense of the vectors representing the currents and e.m.f.'s. This is most conveniently done by numbering all the junction points in the network, and designating each current and e.m.f. by a double subscript written in the order corresponding to the assumed direction of the current or e.m.f. vector. For example, in Fig. 9, the e.m.f. from 0 to 1 is represented by $\dot{E}_{01}$ while the e.m.f. from 1 to 0, which is equal to $-\dot{E}_{01}$, is represented by $\dot{E}_{10}$. In the figure, then, the net electromotive force from 1 to 2 is

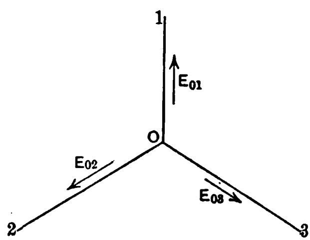

Fig. 9.

$$\dot{E}_{12} = \dot{E}_{10} + \dot{E}_{02},$$

or

$$\dot{E}_{12} = -\dot{E}_{01} + \dot{E}_{02}.$$

Each equation of the form (31) or (32) is in reality equivalent to two equations, since the sum of all the "real" terms on one side must be equal to the sum of all the real terms on the other side, and similarly, the sum of all the "j" terms on one side must be equal to the sum of all the "j" terms on the other side, the denominators of all fractions having been cleared of "j" terms by the transformation given by equation (30). This is merely another way of stating the fact that the component in any direction of the *resultant* of any number of vectors

* These relations are simply Kirchhoff's Laws (*see Electricity and Magnetism, Principles of*) expressed in a convenient form for alternating currents.

must be equal to the algebraic sum of the components in this direction of all the individual vectors. Applying these two laws to any network enables one, therefore, to calculate both components of every p.d. and every current, when the impedances and the electromotive forces are known.

These equations hold only when *the currents and e.m.f.'s are all simple harmonic functions* of the *same* frequency *and the resistances and reactances are constant.* When, however, the resistances, inductances and capacities are constant, a similar set of equations holds for each frequency that may be present. Since the equations are all linear in the I's and E's, the currents and e.m.f.'s of any given frequency will be uninfluenced by the presence of currents or e.m.f.'s of any other frequency. Hence, when the harmonics present in each e.m.f. are known, the harmonics present in each current may be calculated by solving the equations corresponding to the frequency of this particular harmonic, these equations being exactly the same as would hold were all the other harmonics absent.

Note particularly that the above equations do not hold for transient currents; they apply only after the transient terms have become zero. See *Transient Electric Phenomena and Oscillations.*

Difference in Phase between a Current and Voltage in Symbolic Notation. — Let the current be represented by

$$\underset{\cdot}{I} = I_1 + jI_2$$

and the voltage drop in the same sense as the current be represented by

$$\underset{\cdot}{V} = V_1 + jV_2.$$

Then the current lags behind the voltage drop by the angle θ, where

$$\tan\theta = \frac{V_2I_1 - V_1I_2}{V_1I_1 + V_2I_2}. \tag{33}$$

Power Corresponding to a Current and Voltage in Symbolic Notation. — Let the current and voltage drop be represented by the same expressions as in the preceding paragraphs. Then the average power is

$$P = V_1I_1 + V_2I_2. \tag{34}$$

Note that this expression is equal to the real part of the product of the complex numbers $V_1 + jV_2$ and $I_1 + jI_2$ *with the sign between the two terms reversed.*

Example of the Use of the Symbolic Method. — An impedance z_1 has a resistance of 3 ohms and an inductive reactance of 4 ohms; a second impedance z_2 has a resistance of 8 ohms and a condensive reactance of 6 ohms. z_1 is then represented symbolically as $\underset{\cdot}{z_1} = 3 + j4$ and z_2 as $\underset{\cdot}{z_2} = 8 - j6$.

Let these two impedances be connected in series, and let an e.m.f. of 100 volts be impressed across them. Choosing the vector representing the over-all potential drop as the axis of reference, and calling the current I, then $(3 + j4 + 8 - j6)\,\underset{\cdot}{I} = 100 + j0$, whence

$$\underset{\cdot}{I} = \frac{100}{11 - 2j} = \frac{1100 + j200}{121 + 4} = 8.8 + j1.6.$$

Hence the effective value of the current is

$$I = \sqrt{(8.8)^2 + (1.6)^2} = 8.94 \text{ amperes}$$

and the current leads the over-all potential drop by the angle

$$\tan^{-1}\frac{1.6}{8.8} = 10.3°.$$

The potential drop across the first impedance is

$$\underset{\cdot}{V'} = (3 + j4)\,(8.8 + j1.6) = 26.4 - 6.4 + j\,(35.2 + 4.8) = 20 + j40,$$

which has the effective value

$$V' = \sqrt{(20)^2 + (40)^2} = 44.7 \text{ volts},$$

and leads the over-all potential drop V by the angle

$$\tan^{-1}\frac{40}{20} = 63.5°.$$

The potential drop across the second impedance is

$$V'' = (8 - j6)(8.8 + j1.6) = 70.4 + 9.6 - j(52.8 - 12.8) = 80 - j40,$$

which has the effective value

$$V'' = \sqrt{(80)^2 + (40)^2} = 89.4 \text{ volts},$$

and lags behind the over-all potential drop V by the angle

$$\tan^{-1}\frac{40}{80} = 26.5°.$$

The power input into the first impedance is

$$W' = 8.8 \times 20 + 1.6 \times 40 = 240 \text{ watts}.$$

The power input into the second impedance is

$$W'' = 8.8 \times 80 - 1.6 \times 40 = 640 \text{ watts}.$$

The total power input is

$$W = 8.8 \times 100 + 1.6 \times 0 = 880 \text{ watts},$$

which of course is the sum of W' and W''.

POLYPHASE SYSTEMS. -- A polyphase alternating-current system is a network (i.e., combination of circuits) supplied from a generator or generators which develop two or more electromotive forces differing in phase from one another by a constant angle; see *Distribution of Electric Energy; Generators, Alternating-current; Transformers.* The two kinds of polyphase circuits commonly employed are the two-phase and three-phase circuits.

Star and Mesh Connections. — Consider n separate coils or windings, which may be mounted on a common armature or be entirely distinct, as for example n groups of lamps. When these n windings are connected end to end so that they are all in series, forming a closed chain, as in Fig. 10, and terminals

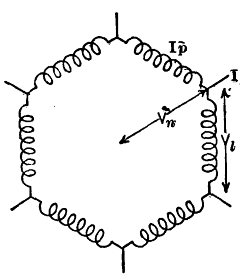

Fig. 10.

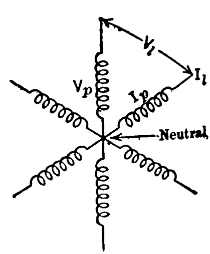

Fig. 11.

are brought out from the n junctions, they are said to be connected in "mesh." When one terminal of each of these windings is connected to a common junction point, as in Fig. 11, and terminals are brought out from the free ends, the windings are said to be connected in "star," and the common point is called the "neutral point."

n-Phase System. — When such a group of n windings, as shown in Fig. 10 or 11, is connected to a generator or other source of e.m.f., having n separate windings and therefore developing n different e.m.f.'s which differ in phase from one another, the system is called an n-phase system, each winding being called a "phase." For example, when there are three separate windings on the generator, three line wires and three windings constituting the load, the system is a three-phase system.

Balanced Systems. — When the e.m.f.'s, if any, in the n-phases of any system of connection are all equal in effective value and differ successively in phase by $360/n$ degrees and if the currents in these windings are also equal in effective value and differ successively in phase by $360/n$ degrees, the system is said to be a "balanced" n-phase system. When the e.m.f.'s in the various parts of a system are equal in effective value and differ successively in phase by $360/n$ degrees, and the impedances in the various windings or phases are all equal, both as regards resistance and reactance, then the currents are necessarily equal in effective value and differ successively in phase by $360/n$ degrees, and the system is balanced.

Phase and Line Currents and Voltages. — The current in any winding or phase of an n-phase system, see Figs. 10 and 11, is called the "phase current," and the drop (or rise) of potential *through* this winding is called the "phase voltage." The current in the line leaving any terminal of an n-phase system is called the "line current" and the voltage between *adjacent* line wires or terminals is called the "line voltage," except in the special case of a two-phase connection, see below, when the voltage between diametrically opposite terminals is called the line voltage. In the case of a star-connection the voltage between any terminal and the neutral point is called the "voltage to neutral"; in the case of a balanced mesh connection by voltage to neutral is meant the voltage which would exist between any terminal and the neutral of a star-connection connected to the terminals of the actual device, the impedance of all the legs of the star-connection forming this "artificial neutral" being equal and sufficiently large not to take an appreciable current.

The relations between these various currents and voltages for a balanced n-phase system are as follows:

	Mesh	Star
Number of phases	n	n
Line current	I_l	I_l
Line voltage	V_l	V_l
Phase current	$I_p = \dfrac{1}{2\sin\frac{\pi}{n}} I_l$	$I_p = I_l$
Phase voltage	$V_p = V_l$	$V_p = \dfrac{1}{2\sin\frac{\pi}{n}} V_l$
Voltage to neutral	$V_n = \dfrac{1}{2\sin\frac{\pi}{n}} V_p$	$V_n = V_p$
Total volt-amperes	$nV_pI_p = \dfrac{n}{2\sin\frac{\pi}{n}} V_lI_l$	$nV_pI_p = \dfrac{n}{2\sin\frac{\pi}{n}} V_lI_l$

Two-phase or Quarter-phase System. — Strictly, the so-called single-phase system is a star-connected two-phase system, since the currents *from* the two terminals are in opposite directions at any instant, the current leaving by one and entering by the other. However, in practice the name two-phase system is used for a system supplied from a generator or other source of e.m.f. having two windings in which are developed two e.m.f.'s differing in phase by 90°; i.e., a two-phase system is in reality two distinct single-phase systems each with two terminals. Two of the four terminals may be connected to each other, in which case but three line wires are required. Or, the two single-phase systems may be connected at their middle points; in this case the two-phase system may be considered as a four-phase, or, as it is usually called, a "quarter-phase" system. See the articles on *Distribution of Electric Energy* and *Transformers.*

Three-phase System. — Delta and Y-Connections. — For a three-phase system the generators and motors are designed with three windings or phases which may be connected either in mesh, usually called a "delta-connection" in this case, since the diagram of the three windings forms a Greek delta, or the three windings may be connected in star, usually called a "Y-connection" in this case, since the diagram of the three windings forms a Y. The relations between line and coil currents and voltages for a *balanced* three-phase system are as follows:

	Delta	Y
Line current	I_l	I_l
Line voltage	V_l	V_l
Phase current	$I_p = \frac{I_l}{\sqrt{3}}$	$I_p = I_l$
Phase voltage	$V_p = V_l$	$V_p = \frac{V_l}{\sqrt{3}}$
Voltage to neutral	$V_n = \frac{V_l}{\sqrt{3}}$	$V_n = V_p$
Total volt-amperes	$3V_pI_p = \sqrt{3}V_lI_l$	$3V_pI_p = \sqrt{3}V_lI_l$

Calculation of Balanced Three-phase Circuits. — Any problem in regard to a *balanced* three-phase circuit may therefore be solved by reducing all parts of the circuit to an equivalent Y-connection, provided the currents and e.m.f.'s are sine-waves. The transformations are made as follows:

Any Δ-connected motor or generator is considered as equivalent to a Y-connected generator or motor in which

$$E_y = \frac{E_\Delta}{\sqrt{3}}, \qquad r_y = \frac{r_\Delta}{3}, \qquad x_y = \frac{x_\Delta}{3},$$

where the quantities E_y, r_y and x_y are the e.m.f., resistance and reactance per phase of the Y-connected machine equivalent to the e.m.f., resistance and reactance per phase of the actual Δ-connected machine.

Each of the line wires is in series with a corresponding phase of the equivalent Y-connected machine.

When all parts of the circuit have thus been reduced to equivalent Y's, each of the three-phases may be treated as a single-phase circuit, each circuit considered completed by a wire having *zero* impedance connecting all the neutrals together, since all the neutrals are at the same potential.

The voltages thus calculated are the voltages to neutral and the currents are line currents. To find the line voltage multiply the calculated voltage by $\sqrt{3}$; similarly, to find the actual phase current in the Δ-connected generator or load divide the calculated current by $\sqrt{3}$.

Example of Three-phase Calculation. — Energy is supplied from a generating station to a substation 50 miles away at a rate of 20,000 kilowatts. The system is a balanced three-phase system and operates at a frequency of 25 cycles. The transmission line consists of three No. 0000 B. & S. copper wires spaced six feet between centers. It is desired to find (1) the voltage between wires at the generating station when the voltage between wires at the substation is 60,000 volts, and the power factor at the substation is 80 per cent, with the current *lagging*, (2) how much power is lost in the transmission line and (3) what is the power factor at the generating station. The electrostatic capacity of the line may be neglected.

The current per wire is

$$I = \frac{20{,}000{,}000}{\sqrt{3} \times 60{,}000 \times 0.8} = 241 \text{ amperes.}$$

The voltage to neutral at the substation is

$$V_n = \frac{60{,}000}{\sqrt{3}} = 34{,}600.$$

The component of this voltage in phase with the line current is $0.8 \times 34{,}600 = 27{,}700$ volts and the component 90° ahead of the line current is $0.6 \times 34{,}600 = 20{,}800$ volts, since $\cos\theta = 0.8$ and $\sin\theta = 0.6$.

The resistance per mile of a No. 0000 wire is 0.258 ohm; its reactance per mile at 25 cycles is 0.303 ohm. Hence the total resistance of each wire is 12.9 ohms and the total reactance of each wire 15.2 ohms. The resistance drop in each wire is then $12.9 \times 241 = 3110$ volts and is in phase with the line current and the inductive drop in each wire is $15.2 \times 241 = 3660$ volts and is 90° ahead of the line current.

At the generator end the voltage to neutral in phase with the line current is then $27{,}700 + 3110 = 30{,}810$ volts and the voltage to neutral 90° ahead of the current is $20{,}800 + 3660 = 24{,}460$ volts. The resultant voltage to neutral at the generator end is then $\sqrt{(30{,}810)^2 + (24{,}460)^2} = 39{,}300$ volts, and therefore the line voltage at the generating station is

$$V_l' = \sqrt{3} \times 39{,}300 = 68{,}000.$$

The power lost in the line is equal to $3RI_l^2$, where R is the total resistance of each wire and I_l the line current. Hence the power lost in the line is

$$3 \times 12.9 \times (241)^2 \text{ watts} = 2250 \text{ kilowatts.}$$

The total power delivered to the line and substation is then 22,250 kilowatts. Hence the power factor at the generating station is

$$\frac{22{,}250{,}000}{\sqrt{3} \times 68{,}000 \times 241} = 0.784 = 78.4 \text{ per cent.}$$

Measurement of Power in Three-phase Circuits. — See *Wattmeters*.

ALUMINUM. — (*See also Electrochemical Processes, Industrial; Lightning Protectors; Wires and Cables, Bare.*) The method of manufacturing aluminum wire is similar to that employed in making copper wire (*see Copper*).

MECHANICAL PROPERTIES. — The more important mechanical properties of aluminum are discussed below.

Necessity of Stranding Aluminum Wire. — Aluminum wire (i.e., solid wire) is little used for aerial spans owing to the danger of failure where accidental abrasions have occurred. Cables not only reduce the above danger, but have greater breaking load, owing to the superior tensile strength of small wires.

Tensile Strength. — The tensile strength of aluminum has not been studied so thoroughly as that of copper, but it is well known that like copper, aluminum is much stronger in small, than in large, wires. The following table by H. M. Hobart, which is for solid wires, illustrates this point.

Diameter, inches	0.05	0.10	0.15	0.20	0.25	0.30	0.35
Tensile strength, lb. per sq. in.	33,300	28,800	26,200	24,800	23,800	23,200	23,000

The Standard Electric Co., of California, uses a solid aluminum wire, 0.294 inch diameter, having a tensile strength of 22,800 pounds per square inch, and a conductivity of 59.9 per cent.

Elongation. — The ultimate elongation of hard-drawn aluminum wire varies from 2.0 per cent to 3.7 per cent (in 1 meter length) as the diameter is increased from 1 to 4½ mm. (*H. M. Hobart.*)

Modulus of Elasticity. — Different authorities give values from 9×10^6 to 10×10^6 in pounds per square inch, the former being given by the Aluminum Company of America.

Elastic Limit. — The Aluminum Company of America in their booklet on "Properties of Aluminum," Pittsburg, 1909, give the following figures for elastic limit in tension, the metal being 99 per cent pure.

	Lb. per sq. in.
Castings	8,500
Sheet	12,500 to 25,000
Wire	16,000 to 33,000
Bars	14,000 to 23,000

Density. — A density of 2.70 grams per cubic centimeter is given by the U. S. Bureau of Standards (*Circ. No. 31*) as a good average value for commercial hard-drawn aluminum. This is equivalent to 0.0975 pounds per cubic inch. Hobart gives 2.71 for the density. F. J. Brislee (*Lond. Elec. Review, Jan. 5, 1912*) gives 2.708 as the density of cast aluminum and 2.705 for hard-drawn rod.

THERMAL PROPERTIES. — See article on *Heat and Thermal Properties*.

CONDUCTIVITY AND RESISTIVITY. — The Aluminum Company of America give as the average of many thousands of separate determinations, the figure of 2.828 microhms per centimeter cube at 20° C. as the conductivity of commercial aluminum wire.

Effect of Hardness on Conductivity. — The resistance of aluminum depends upon its hardness; for example, the resistance of aluminum wire of hard-

mately 2 per cent greater than that of the same wire when thoroughly annealed and consequently soft. (*H. M. Hobart.*)

Temperature Coefficient of Resistivity. — This is given by M. Dusaugey as 0.00402 per degree centigrade.

COMPARISON OF ALUMINUM AND COPPER. — Aluminum is usually cheaper than copper of the same length and resistance and is said to be cheaper to install (*C. B. Smith, El. W., 1912, Vol. 59, p. 96*). It is, however, subject to the disadvantage of lower tensile strength which often makes it more expensive than copper, except for very high voltages.

The table below compares the various items for wires having the same length and same resistance and is based on the following assumptions:

	Copper	Aluminum
Per cent conductivity	98	61
Tensile strength, lb. per sq. in.	55,000	25,000
Density	8.89	2.70
Price per pound	P	p

COMPARISON OF COPPER AND ALUMINUM WIRES FOR EQUAL RESISTANCES PER UNIT LENGTH

Item	Copper	Aluminum
Cost	1	$0.488 \times \frac{p}{P}$
Cross-section	1	1.63
Diameter	1	1.28
Weight	1	0.488
Breaking strength	1	0.731
Carrying capacity	1	1.13

Disadvantage of Low Tensile Strength. — The lower tensile strength of aluminum for equal length and conductance as compared with copper affects the cost of an aerial line in two ways; 1st, by making it necessary to erect the spans with a greater sag or less length in order to reduce the stresses, thereby either increasing the height or the number of poles, and 2nd, by making it necessary to increase the distance between wires on account of the increased sag. The increase in the height of poles for the same spacing amounts to about 10 per cent, (*C. L. Johnson*).

Effect of Large Elongation of Aluminum. — The extraordinarily great elongation of aluminum enables it to withstand severe mechanical overloads by stretching and thus increasing the sag. However, in dealing with a single solid wire this cannot be relied on, as a scratch or a single imperfection will often cause the wire to break without any appreciable elongation. This is one reason why cables are to be preferred to single-wire conductors.

Effect of Low Melting Point of Aluminum. — The distance between aerial wires is also influenced by the fact that aluminum has a lower melting point than copper, making it necessary to keep wires at different potentials well separated in order to avoid the danger of short-circuits through foreign bodies. This danger has, perhaps, been exaggerated in the past as the author has the

record of a case where a copper wire was thrown across two aluminum cables with 60,000 volts difference of potential between them and an arc was formed between the cables forming an arch 12 to 15 feet high, but with no injury to the cables except the formation of a few minute beads on their surface.

Formation of Sleet. — While for equal length and resistance, aluminum wires are larger than copper wires, they do not necessarily collect a proportionally greater load of sleet, as it is found that a film of grease left over from the drawing process often entirely prevents the adhesion of sleet. Conclusive information on this subject is, however, lacking, especially with regard to wire that has been in use for several years.

Corona Formation. — At very high potentials, such as 100,000 volts, aluminum conductors possess a marked advantage over copper in the lower corona loss due to their greater diameter for the same conductance.

Corrosion. — E. Huber-Stockar gives the results of a number of recent tests on the corrosion of aluminum in moist air, salt air, salt water, various gases, acids, etc., which indicate that, in respect to its chemical stability, aluminum is in general the equal of copper. There has been much said about the tendency of electrostatic repulsion to reduce impure condensation on aluminum conductors, but this author rejects such statements as unworthy of the slightest credence.

Bare aluminum conductors laid in the earth have been tried for railway return feeders, with the result that they were rapidly corroded by galvanic action.

Mr. Dusaugey says that aluminum containing over 4 per cent of impurities is very liable to corrode rapidly. This is especially the case if sodium is present.

At ordinary temperatures aluminum is covered with a layer of oxide which protects it against the influence of the weather and of many chemicals.

Example of Relative Cost. — According to the official publications of the Ontario Hydro-Electric Commission on a line consisting of two three-phase circuits, each comprising three 0000 A.W.G. cables, the six cables cost $1450 per mile as compared with $2050 per mile for copper cables (copper being at 16 cents per pound and aluminum at 23.5 cents per pound), showing a saving of nearly 30 per cent on the cables alone. This saving was reduced to 5.6 per cent only on the total cost of the line, partly because the actual towers weighed 1.72 tons against 1.57 tons for towers for an equivalent copper line, and partly because the cost of cables was only 30 per cent of the total cost of the line, including erection but excluding rights-of-way. (*C. L. Johnson.*) Owing to a tariff of 3½ cents per pound the price of aluminum is higher in the United States than in Canada and Europe, so that the saving would have been considerably less at United States prices.

SPREE-ALUMINUM. — E. Huber-Stockar gives considerable data on an aluminum alloy, known under the name of spree-aluminum. It has nearly double the strength of pure aluminum. Its breaking length is 10.7 kilometers, as compared with 10.3 kilometers for steel, 6.7 kilometers for aluminum and 5.1 kilometers for hard copper. The use of spree-aluminum cable shows a saving in cost of about 7.3 per cent as compared with copper cable of equal conductance.

[W. A. DEL MAR.]

AMMETERS. — (*See also Balances, Current; Electricity and Magnetism, Principles of; Electrodynamometers; Galvanometers; Voltmeters.*) An ammeter is essentially a galvanometer (q.v.) or electrodynamometer (q.v.) of rugged construction, provided with a pointer moving over a scale forming an integral part of the instrument and calibrated to read directly in amperes. The moving element is usually supported in jeweled bearings.

CLASSIFICATION AND USE OF AMMETERS. — Ammeters which have found general commercial application may be classified as follows:

Moving-magnet Type, in which a permanent magnet or polarized vane is caused to move under the influence of a winding which carries the current to be measured. The principle of operation is similar to that of a Thomson galvanometer (*see Galvanometers*). The restoring force is usually a fixed permanent magnet. This type of meter measures average values and is therefore suitable for direct currents only.

Soft-iron Vane (or Plunger) Type, in which a soft-iron vane or plunger is caused to move under the influence of a winding carrying the current to be measured; a fixed piece of iron may be included near the moving vane or plunger, so magnetized with relation to the latter that either attraction or repulsion between it and the vane or plunger takes place under the influence of the current. The restoring force may be either gravity or a spring. This type of meter measures effective (r.m.s.) values* and may be used for either alternating or direct currents, but such meters are subject to slight errors in the latter case, due to the tendency of the vane or plunger to hold its magnetism.

Thomson Inclined-coil Ammeter (Fig 1). — This is a moving-vane instrument, the essential features of which are shown in Fig. 1. The stationary coil makes an angle of approximately 45 degrees with the shaft upon which the soft-iron vane is mounted. The vane, which is mounted on the shaft, also makes an angle of approximately 45 degrees with the shaft. When the pointer is in the zero position the plane of the vane coincides very nearly with the plane of the coil, being therefore nearly perpendicular to the magnetic field which would be produced by a current in the coil. When a current is sent through the coil the vane tends to set itself parallel to the magnetic field, since by so doing the reluctance of the path of the flux produced by the coil is diminished (*see Electricity and Magnetism, Principles of*). The torque exerted on the vane by the magnetic field is balanced by the opposing torque of the spring, so that for a definite value of the current through the coil the needle takes up a definite position.

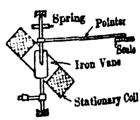

Fig. 1.

Moving-coil Type, in which a permanent magnet maintains a strong field in a fixed location, and the current to be measured is sent through a moving coil, entering or leaving by springs that furnish the restoring force or through auxiliary spirals. The principle of operation is the same as that of a D'Arsonval galvanometer (*see Galvanometers*). This type of meter measures average values and is suitable for direct currents only. Precision d-c. ammeters are usually of this type.

* Moving-vane or plunger instruments do not measure r.m.s. values exactly, on account of the lack of exact proportionality between the instantaneous torque and the square of the instantaneous current, but by careful attention to details in the design such instruments can be made nearly perfect in this respect, so that all things considered, they are sometimes to be preferred to the dynamometer-type instruments. For precise work calibration of such instruments made with direct current should not be used on

Electrodynamometer Type, in which the effect of one conductor carrying a current moving under the influence of a fixed coil carrying the same current, and joined in series to the moving coil, is utilized (*see Electrodynamometers*). In these instruments the restoring force is sometimes gravity, but is usually due to springs, and the current is led into and out of the moving coil through these springs or through flexible conductors constructed to carry relatively large currents and to have a minimum restoring force. This type of instrument measures effective (r.m.s.) values and may be used to measure either alternating or direct currents. Precision a-c. instruments are usually of the electrodynamometer type.

Hot-wire Type, in which the expansion of a wire or strip due to the heat developed within it, caused by the current passing through it, is made to move an indicating pointer. The "thermocouple" ammeter, described below, may also be classified as a hot-wire ammeter, although the principle of operation is quite different. Hot-wire meters measure effective (r.m.s.) values and are useful for both alternating- or direct-current measurements.

Induction Type, in which a metal cylinder or disk with pointer attached is caused to rotate under the action of a rotating magnetic field, usually produced from a single-phase source by means of a phase-splitting device. The principle of operation is similar to that of an induction watt-hour meter (*see Watt-hour Meters*), the motion of the moving element being opposed by a spring. This type of instrument measures effective values and is suitable for alternating currents only and generally for only a limited range of frequency.

Thermocouple Ammeters. — For measuring small alternating currents, particularly when the frequency is high (500 cycles per second or more), a thermocouple (*see Pyrometers*) may be used; the current to be measured is passed through a wire resistor (*see Wires, Resistor*) to which is soldered one junction of the thermocouple, the free ends of which are connected to an ammeter (or galvanometer) of any of the types noted above. The heating of the resistor wire sets up a direct current in the thermocouple circuit which, in turn, depends upon the effective value of the current through the heater wire. The limitations and errors in the use of such meters are discussed at length in a paper on *High Frequency Ammeters* in Scientific Paper, No. 206, Bull. Bur. Stds., 1913, Vol. 10.

Other Types of Ammeters. — Successful instruments for special needs have been made that would not ordinarily be classed under the above headings, and other instruments might be referred to which combine in a single instrument more than one of the subdivisions.

Portable and Switchboard Instruments. — Switchboard instruments are usually of more rugged construction than portable instruments and are somewhat less precise in their indications. Portable instruments are provided with suitable binding posts on their bases and are usually used in a horizontal position. Switchboard meters are usually provided with back connections and are used in a vertical position. In the so-called "edgewise" instruments the meter mechanism is horizontal but the pointer is so designed that it registers on a scale in a vertical plane.

Curve-tracing Ammeters. — A continuous record of current may be obtained by using an ammeter provided with a clock mechanism which slowly rotates a chart (disk-shaped or mounted on a drum) or a continuous paper ribbon under the end of the pointer which carries a pen kept continuously inked. The moving element in such meters is comparatively heavy since the deflecting force must be great enough to overcome the friction of the pen and prevent "sticking."

METER SCALES. — A uniform scale is usually desirable in any kind of meter, and with permanent-magnet types such a scale is readily obtained, since

the deflecting torque is proportional to the current. In moving-vane, electrodynamometer types and other types in which the deflecting torque depends upon the square of the current, very small deflections are obtained for low values of the current and the scale divisions are crowded for low values.

DAMPING. — For ordinary purposes it is essential that the pointer of the meter come quickly to rest. The moving coil of the moving-coil instruments is usually wound on a light metallic frame (aluminum) which is mounted between the poles of the permanent magnet, and a soft-iron core fills the air gap between the poles, other than that necessary to allow free motion of the coil. The result is that the metal frame moves through a very strong magnetic field and eddy currents are set up in the frame which effectually damp its motion. Although it is not difficult to make the instruments perfectly aperiodic, it is seldom advisable to have as much damping as this, for a slight underdamping gives opportunity to observe at all times that the movement of the instrument is perfectly free.

Magnetic (eddy current) damping or air damping by means of light vanes moving in a more or less perfectly closed air chamber is used with the other types of instruments.

ELIMINATION OF EFFECT OF STRAY FIELDS. — Due to the low reluctance of iron compared with air, a soft-iron shield placed around the meter mechanism will prevent, at least to a large degree, any external magnetic field from producing any effect on the moving element of the meter. Many types of switchboard and portable instruments are thus shielded. Permanent-magnet instruments are affected by only comparatively strong fields.

Astatic Instruments. — Another means of avoiding errors due to stray fields is by making the moving element astatic. The principle of this construction is to divide the moving element into two parts, so arranged that the deflecting torque acting on the two parts due to the field of the instrument are additive, whereas any stray field will produce equal and opposite torques on these two parts.

Thomson Astatic Meters. — The Thomson astatic ammeters and voltmeters are well-known instruments of this class. These instruments are also unique in that the deflecting torque and the controlling torque are both caused by the same magnetic field. This field is produced by an electromagnet wound for any specified voltage and provided with binding posts separate from the current posts of the instrument, or by means of a permanent magnet. Two moving coils are mounted diametrically opposite each other upon an aluminum disk. The disk and coils cut across the field which is directed parallel to the shaft carrying the disk. Two small pieces of soft iron are rigidly mounted on the shaft, the magnetic field entering these pieces of iron radially, tending to hold the shaft and moving coils in their initial position.

When current passes through the coils of the moving element, the lines of force parallel to the shaft produce a torque which tends to turn the shaft and cause the needle to travel across the scale. This action is opposed by the magnetic field at right angles to the shaft acting on the two pieces of soft iron. The instrument has no controlling springs and since both the deflecting and controlling force are due to the same electromagnet, the accuracy is not affected by changes in magnetic strength. These instruments are particularly suited to service where very strong external fields are present.

USE OF SHUNTS AND CURRENT TRANSFORMERS. — (*See also articles on Shunts; Transformers, Instrument.*) The current which may be led into the moving element of an ammeter (moving-coil or electrodynamometer type) is limited by the current-carrying capacity of the springs or special lead-

10 amperes. To increase the range of such instruments, and also to avoid the use of heavy conductors in the instruments, shunts or current transformers (the latter for alternating currents only) are used. Ammeters for use with current transformers are usually designed to take a maximum current of 5 amperes, but their scales are calibrated to read directly the current in the primary of the transformer.

Millivoltmeter Used as Ammeter. — Direct-current ammeters designed for use with shunts are usually designed to carry but a very small current (usually 0.025 ampere). A non-inductive resistance, made of a wire resistor having practically zero temperature coefficient, is permanently connected, within the case of the instrument, in series with the moving coil. The combined resistance of the moving coil and resistance coil is thus made large compared with the resistance of the shunt, and the error is not large for ordinary changes in temperature. The ammeter proper is then essentially a millivoltmeter (*see Voltmeters*) and measures the drop of potential through the shunt to which it is connected; the scale of the ammeter, however, is usually calibrated to read directly in amperes for one or more standard shunts designed for use with it.

Voltage Drop Across Shunts. — Shunts for use with direct-current ammeters of the moving-coil type are usually designed for a drop of 60 millivolts at full load, although for some special requirements, where the indicating instrument must be located at a considerable distance from the shunt, double-drop shunts having 120 millivolts are used, and even higher drops are used to meet very special requirements. For precision use with portable instruments the resistance coil is so designed that a drop of 200 millivolts is required for full-scale reading, the high resistance with zero temperature coefficient practically eliminating all temperature errors.

Use of Portion of Bus Bar as Shunt. — Sometimes the shunt is dispensed with altogether and the millivoltmeter is attached directly to a portion of the bus bar or main conductor. This arrangement is usually not desirable, because the variation of temperature in the bus bar due to the current flowing through it causes larger errors than the variation due to changes in room temperature. Some arrangements have been made to compensate for these, but are not very generally used.

Voltmeter and Shunt for Measuring Alternating Currents. — An a-c. voltmeter with shunt is not in general suitable for measuring an alternating current, since such meters are not readily constructed to read low voltages and therefore a relatively large drop in the shunt would be required, also the division of current between the shunt and voltmeter depends (1) upon the inductances of the shunt and meter, (2) upon the "skin effect" (q. v.) in the shunt. However, hot-wire voltmeters with shunts are sometimes used for alternating-current measurements and are satisfactory at commercial frequencies.

PRECAUTIONS IN USE OF PORTABLE AMMETERS. — The following precautions, which in the main also apply to other portable electrical instruments, should be observed:

Ammeters are subject to most of the errors which affect the accuracy of voltmeters, but usually to a less degree; see article on *Voltmeters*.

An ammeter should always be connected in series with the load. Never connect it across the mains.

All contact surfaces of nuts, terminals, etc., must be clean.

Transformers and wires carrying heavy currents should be kept at a safe distance from all meters.

Portable instruments should be always used in a horizontal position, unless specifically designed for use otherwise.

The tapping of the dial of the instrument before making a reading in order to make sure that the moving element does not "stick," is liable to do more harm than good.

It is a good plan in testing to place a low-resistance shunt or short-circuit block * or switch around the terminals of the meter and to connect a rheostat in series with it and the load. The plug of the short-circuit block should be gradually withdrawn, or the switch gradually opened, and the needle of the ammeter watched to be sure that the current is in the right direction and does not exceed the rated current of the instrument.

A heavy short-circuit in nearby conductors, even though of extremely short duration, is liable to demagnetize the magnet of a permanent magnet instrument. After such a short-circuit the meter should be recalibrated, even though the short-circuit causes no mechanical injury.

Transformers and shunts are designed for use with any ammeter, but for very precise work the transformer and meter, or shunt and meter, should be calibrated together or proper corrections made by calculation; see below under *Calibration of Ammeters* and also the article on *Wattmeters*.

When it is desired to measure the average value of a pulsating current (e.g., from a rectifier), permanent-magnet instruments should be used.

Meters containing iron should not be used for a frequency differing largely from that for which the meter is designed. For high-frequency measurements (above 500 cycles per second), some type of hot-wire or thermocouple meter should be used. Ordinary hot-wire instruments used with shunts, or so designed that two or more sections of the hot wire are connected in parallel, are liable to give incorrect readings at frequencies above 500 cycles per second.

Instruments containing iron are also subject to errors due to distorted current waves; for precise work on badly distorted waves they should be compared with an electrodynamometer-type or hot-wire instrument, using the same current in the comparison as that to be measured.

CALIBRATION OF AMMETERS. — The readings of two or more ammeters may be compared by connecting them in series with a rheostat (q.v.) and suitable source of e.m.f. An ammeter may thus be compared with a standard meter, and a curve drawn showing the true amperes corresponding to the dial readings. It is usually more convenient to plot the correction to be made to the reading against the actual reading. Corrections to be added to the reading are usually designated as + and corrections to be subtracted from the reading as −.

Instead of using a standard ammeter, a standard millivoltmeter and a standard resistor (*see Resistors, Standard*) may be employed for calibration on direct current. The standard resistor is connected in series with the ammeter to be calibrated and the millivoltmeter is connected across the potential terminals of the resistor. Let V be the reading of the millivoltmeter in volts, R the resistance of the resistor and r the resistance of the millivoltmeter and then the current measured is

$$I = \frac{V}{R} + \frac{V}{r}.$$

The last term V/r is usually negligible.

An accurate and convenient way of calibrating an ammeter on direct current is to use a potentiometer (q.v.), when such an instrument is available.

Calibration of A-C. Ammeters. — Alternating-current indicating instruments whose deflections are independent of frequency and wave form when

* For light testing two blocks of metal mounted on an insulating base with a tapered hole between the two, into which fits a tapered metal plug, makes a convenient short-

calibrated on direct-current indicate correctly effective values when used on alternating current. Electrodynamometer-type instruments usually give readings of equal accuracy on alternating or direct current at commercial frequencies and wave form. Eddy currents in the metal supports and conductors, however, may cause slight errors in some makes, even at commercial frequencies, and for high frequencies errors are liable to occur in all types unless special precautions are taken to avoid eddy currents. Soft-iron and induction-type ammeters should be compared with an electrodynamometer-type meter which has been previously calibrated on direct current.

PRECISION OF AMMETERS AND OTHER ELECTRICAL METERS. — It is customary to express the accuracy of an electrical instrument provided with a pointer and scale in terms of the per cent of *full scale reading;* i.e., calling S the full scale reading, e the *maximum* error of a single reading at any point of the scale, as a fraction of a single scale division, then the percentage error is $p = \frac{100\,e}{S}$. It should be noted, however, that the scale reading is usually less than the full amount, and therefore, the error as a per cent of the actual reading will be greater the smaller the actual scale reading. On the other hand, the actual errors in graduating and reading scales are not as large at the lower part of the scale as they are higher up, so that although the error as a per cent of the actual reading is greater the nearer to zero the reading is, this error is not quite inversely proportional to the size of the deflection.

Again, the average error, expressed as a fraction of a single scale division, for several readings taken at different parts of the scale will probably be less than the error of a single observation expressed as a fraction of a single scale division, corresponding to the stated percentage error of the instrument.

From the above it is evident that any brief statement of the accuracy of such instruments, although carefully guarded, are apt to be misunderstood, and may give an erroneous idea of the actual precision which is obtainable with the instrument. However, merely as an indication of the relative degree of precision of the various types of meters, the following figures are given. Portable meters with a stated full scale percentage accuracy of 0.5 per cent are readily obtainable from reliable makers, and when properly calibrated the readings may be relied on to an accuracy of about 0.2 per cent of full scale deflection. The stated full scale percentage accuracy of switchboard instruments is usually not so good, being about ½ to 1 per cent for a high-grade instrument and less for a cheap low-grade instrument, or one having a small scale with heavy divisions.

INSTALLATION OF SWITCHBOARD INSTRUMENTS. — The same general considerations apply to all switchboard instruments, i.e., ammeters, voltmeters, wattmeters, etc. Instruments previous to installation should be kept in a dry, cool place. Switchboard instruments should not be put in place until all the work on the boards or in the vicinity of their location has been done so that they may not be damaged by violent shocks.

During shipment moving parts, etc., are sometimes blocked and instructions furnished with instruments by makers should be carefully followed in unpacking and assembling.

It is not customary to ground the cases of d-c. instruments or of a-c. instruments above 650 volts; these are usually protected by insulated covers. Instruments on secondary circuits below 650 volts are usually grounded.

Determination of Capacity of Instruments. — In providing instrument equipment for switchboard service the relation between ammeters, voltmeters, wattmeters and the circuit conditions should be carefully considered so that proper sizes may be provided. The size should be so chosen that a good indication can be obtained under all load conditions, and at the same time the

highest sustained loads can be accurately indicated. Ammeters or current coils of wattmeters should not ordinarily be arranged with shunts or current transformers having a smaller ampere capacity than the instrument scales. Where standard transformer sizes do not exactly meet requirements, it is sometimes advisable to use instruments having 4-ampere current coils on transformers with 5-ampere secondaries, in order to limit the maximum scale readings. This expedient or other means of reducing the maximum wattmeter scale reading may sometimes be employed with advantage in switchboard wattmeters when the power factor is low.

REPAIRS OF INSTRUMENTS. — Most instruments in use at the present time, both for portable and switchboard use, are constructed with the idea of having their parts readily accessible for repair. Instruments, however, are usually, in comparison with other apparatus, very delicate, particularly with reference to the pivots and jewel bearings. Any extended repairs should, therefore, not be attempted unless equipment and experience suitable for the work in hand are available.

COST OF AMMETERS AND VOLTMETERS. — The following figures are approximate only, and should be used only as a rough guide. Shunts and instrument transformers are not included; see articles on *Shunts* and *Transformers, Instrument*.

COST OF AMMETERS AND VOLTMETERS

Type of instrument	Switchboard instruments	Portable instruments
Moving-coil permanent-magnet type:		
Small instruments of cheap construction	\$2–\$3	\$6–\$10
Small medium-grade instruments	\$6–\$8	....
High-grade, large size	\$15–\$50	\$25–\$75*
Moving-magnet type	\$3–\$5	\$2–\$10
Iron-vane type:		
Low-grade	\$5–\$8	\$15–\$25
High-grade	\$20–\$35	\$40–\$60
Hot-wire type, frequency work:		
Low-grade	\$5–\$10	......
High-grade	\$20–\$40	\$20–\$40
Electrodynamometer type:		
Low-grade	......	\$20–\$35
High-grade	\$25–\$50	\$50–\$75
Induction type, high-grade	\$18–\$40	\$30–\$50

* External shunts with low temperature coefficient for use with portable moving-coil millivoltmeters, reading 200 millivolts, cost as follows:

10-ampere shunt	\$12–15	200-ampere shunt	\$30–35
50-ampere shunt	20–25	500-ampere shunt	40–45
100-ampere shunt	25–30	1000-ampere shunt	60–75

Multipliers for 300-volt voltmeters, giving full scale reading for both 600 and 1500 volts cost from \$15 to \$25.

[L. T. Robinson.]

AMPERE-HOUR METERS. — (*See also Ammeters; Wattmeters.*) Ampere-hour or quantity (coulomb) meters may be divided into practically two classes, i.e., electrolytic meters and electromagnetic or motor meters. They are used in this country chiefly for storage-battery work; small capacity ampere-hour meters are also used, particularly abroad, as watt-hour meters, being calibrated in this case to read directly in kilowatt-hours at some definite voltage.

ELECTROLYTIC METERS. — This type of meter is used extensively in Europe, but is rarely used in this country. The meter generally consists of some form of glass container or "U" tube containing an electrolyte, such as water, mercurous nitrate or caustic soda. The action of the current passing through the solution decomposes it and since the rate of decomposition is proportional to the strength of the current, the deposit of metal or the number of cubic centimeters of gas evolved can be calibrated to measure the quantity of current. (*See Electrochemistry, Principles of.*) Such meters can also be used as watt-hour meters (q.v.) in which case they are usually calibrated to read directly in kilowatt-hours at some assumed voltage. In some types the entire current to be measured is passed through the electrolyte and in others the main current passes through a shunt and only a very small part of the current passes through the electrolyte. In a satisfactory design of electrolytic meter the drop at full load does not exceed 1½ to 2 per cent on a 200-volt circuit, and is accurate to within 2 per cent or better (depending on the design) at all loads between 10 per cent and 150 per cent load.

MOTOR METERS. — The essential parts of the motor ampere-hour meter are the motor element, the brake- or speed-regulating device and the register or gear train which records the integrated current passed through the meter. The motor consists of an armature rotating in a magnetic field produced either by a permanent magnet or by an electromagnet. The meters are generally arranged so that only a shunted portion of the current flows through the armature and when electromagnet fields are used they are connected *in series* with the armature. The construction of these motors is otherwise similar to that of a watt-hour meter (q.v.). The commutator and other electromagnetic types of motor meters are all designed with the idea of producing a device which will be cheaper and if possible more rugged than the ordinary watt-hour meter. The absence of a constantly excited "potential circuit" in the meter also avoids the constant loss of energy which takes place in such a circuit irrespective of the load. In the motor meter the drop across the shunt varies in meters of different manufacture from about 50 to 100 millivolts.

Commutator Ampere-hour Meter. — The commutator type of meter in its simplest form consists of a permanent magnet for the fields and an armature with three or more coils and a three- or four-part commutator. In some designs the armature coils are mounted flat on an aluminum disk which in addition to supporting the armature coils produces the retarding or braking action in connection with the field magnet. In another design there is a stationary iron core between the poles of the field magnet and a drum armature rotating in the gap between the stationary iron core and the pole faces of the field magnet. No braking device is used and the motor runs at a speed proportional to the impressed e.m.f., taking only sufficient power to overcome the friction in the bearings and in the gear train.

To compensate for friction at light loads a slight auxiliary potential is sometimes maintained across the brushes by placing the brushes in series with a high resistance across the line or source of power. This arrangement is adjusted so that the meter will not run with no current through the main shunt, but at light load the extra potential difference at the brushes will be sufficient

to speed up the motor enough to make up for loss due to friction of the different moving parts.

Oscillating Motor Ampere-hour Meter. — A special form of the electromagnetic motor meter differing from all other designs is the oscillating meter. In principle, this meter is a clock which is controlled by the current. The hair spring of the clock is replaced by a disk carrying a few small iron wires. This special balance wheel is supported between two coils which carry the current to be measured or a shunted portion of it. The magnetic field from the coils magnetizes the iron wires and in conjunction with the main spring of the clock causes the special balance wheel to oscillate at a rate proportional to the strength of the magnetic field and therefore proportional to the current passing through the meter. The movement of the clock is transferred to a registering mechanism geared to register ampere-hours, or kilowatt-hours at a constant voltage.

Mercury Ampere-hour Meter. — The motor meter of the mercury type utilizes mercury to carry current to the armature, the mercury really taking the place of the brushes and commutator of the ordinary direct-current motor. One form of the meter consists in principle of a copper disk or copper thimble armature mounted in jeweled bearings and immersed in the mercury. The current is led into the mercury chamber through suitable terminals and since mercury has about forty times the resistance of copper, the greater part of this current goes through the copper (approximately diametrically across the disk) and out the other terminal by way of the mercury. This arrangement applies to meters with permanent-magnet fields. In case electromagnet fields are used, the winding is generally divided in two parts on each side of the mercury chamber; also, since the driving torque is proportional to the square of the current, a braking system must be used to produce a retarding force varying with the square of the speed, such as air or fluid friction. When this is done the rate of revolution of the armature when running at a constant speed is proportional to the current passed through the meter. Another method is to use a compensating device to compensate for the increase of fluid friction with increase of speed; this device takes some such form as an auxiliary coil, in series with the motor element, which produces a counter-flux reducing the flux cutting and retarding the disk.

The mercury motor meters utilize iron or in some cases moulded compound for the mercury well, and in the design care must be taken to provide non-spillable joints at the point where the spindle for the armature enters the mercury chamber and to design the magnet so as to insure permanence. All metal in the meters should be of such composition as not to be readily affected by mercury even though not in direct contact with it.

The calibration curve of a mercury motor meter falls off rapidly below 20 per cent load and also falls off rapidly for loads over 100 per cent. Between these limits it is accurate to within 2 per cent or better, depending on the design.

CALIBRATION OF AMPERE-HOUR METERS. — Ampere-hour meters are adjusted and calibrated as follows:

Electrolytic Meters. — As noted above, in the modern types of electrolytic meters mercury is deposited in a glass tube or water is decomposed, the gases passing off in the atmosphere. In the first type a marked scale is placed beside the registering tube into which the electrolyzed mercury falls. This mercury is run back into the mercury reservoir after the reading is taken, by tipping up the cell which is hinged at the top and held vertical by a removable clip at the bottom. To calibrate the instrument an ordinary ammeter may be placed in series with it and the time that the current passes noted on a watch. In testing the types in which gases are evolved and pass off into the atmos-

per division of the scale, which can be done with a graduated burrette. Only the water is decomposed by the passage of the current. To renew the electrolyte after the reading is taken at the end of a period, it is only necessary to add water.

Motor Meters. — In testing motor meters several adjustments are necessary since a shunt, a series-adjusting resistance and the gear train are involved and in addition care must be taken to see that there is no excessive friction in any of the moving parts. The general method is to use suitable standards and with a constant current through the meter to time the revolutions of the armature spindle over at least one-minute intervals, or preferably to determine the time with a stop watch for a certain number of revolutions. Knowing the shunt constant (ratio of total to shunt current) and the register or gear-train ratio, correct speed at a certain current can be calculated and the shunt or adjusting resistance in series with the motor element adjusted to give the correct speed. To determine the accuracy for any set of readings the following formula can be used.

$$\frac{(\text{No. of rev.}) \times (\text{meter constant})}{\text{No. of seconds}} = \text{current.}$$

The "meter constant" is marked on each meter; it is the number of ampere-seconds per revolution of the disk. Meters of this type are not usually as accurate as modern induction and commutator types of watt-hour meters.

WEIGHTS AND COSTS. — Electrolytic meters weigh from 3 to 4 lb. to 15 to 16 lb. Mercury meters of American manufacture weigh about 8 lb. exclusive of shunts. Electrolytic meters cost abroad from \$4 to \$5 each. Motor meters, of both the commutator and mercury types, are made in this country and sell for \$25 to \$30 for small capacities with shunt self-contained. Above 200 and 300 amperes external shunts are furnished. These shunts range in price from \$3 to \$4 for 300 amperes to \$25 or \$30 for 3000 or 4000 amperes.

BIBLIOGRAPHY. — See Bibliography in article on *Ammeters*.

[L. T. ROBINSON.]

ANGLES. — (*See also Trigonometric Functions; Trigonometry.*) Plane angles may be expressed in degrees or in radians. The degree is arbitrarily taken as 1/360th of the plane angle about a point; the radian is defined as the angle subtended by an arc of unit length in the circumference of a circle having unit radius. The angle in radians subtended by any arc of any circle is

$$\text{Angle in radians} = \frac{\text{arc}}{\text{radius}}.$$

The relation between radians and degrees is

$$1 \text{ radian} = 57.30 \text{ degrees.}$$
$$1 \text{ degree} = 0.01745 \text{ radians.}$$

Angle of Curvature. — In railroad practice the angle of curvature is the angle subtended by a chord 100 feet in length, the curve being the arc of a true circle. The relation between degree of curvature D and radius of curvature R is

$$R = \frac{50}{\sin \frac{D}{2}} \text{ feet.}$$

For D small, the chord is very approximately equal to the arc, consequently under these conditions

$$R = \frac{5730}{D} \text{ feet,}$$

where D is in degrees. The error involved in this approximate formula is less than 2 parts in 1000 for D less than 10°, and to less than 1 per cent for D less than 30°. (*See also Railways, Location and Permanent Way for.*)

Solid Angles. — The solid angle at any point P subtended by any surface S is equal to the portion of the surface of a sphere of unit radius which is cut out by a cone having its apex at the point P and its base coinciding with the perimeter of S. The total solid angle about a point is then equal to 4π. The unit of solid angle as thus defined is called a steradian. A solid angle of 2π steradians is called a hemisphere and a solid angle of $\frac{\pi}{2}$ steradians is called a spherical right angle. See table in *Units and Conversion Factors.*

[W. A. Del Mar.]

ARC, ELECTRIC. — (*See also Distribution Systems; Furnaces, Electric; Illumination, Interior and Street; Lamps, Arc; Rectifiers.*) An electric arc is an incandescent vapor bridge consisting of material electrically impelled from a negative to a positive electrode. A spark is also an incandescent vapor bridge, but it differs from an arc, in not depending upon the electrodes for its material medium. The establishment of an arc requires the expenditure of energy for the latent heat of evaporation of the electrode and for the motion of the vapor stream. As no energy can be expended for these purposes until the current flows, an arc cannot start spontaneously. The following expedients are, therefore, adopted to start arcs.

(1) Bringing the conductors into contact with each other and separating them after the current has commenced to flow.

(2) Stressing the dielectric between the conductors until it breaks down electrically and becomes conducting.

(3) Using a subsidiary arc to furnish the initial vapor bridge. The first of these methods is used in carbon-arc lamps and the last in the mercury-arc rectifier.

CARBON ARC. — Until recently the only arc used for illumination was the arc between carbon electrodes, though at the present time there are several materials used, such as magnetite, mercury and the mixtures of various substances with carbon.

Crater. — The vapor column of the carbon arc, impinging on the positive electrode, raises the end of the latter to a very high temperature and volatilizes the carbon. The effect of this is to cause a hollow to be burned in the tip of the positive electrode. This hollow is called the crater.

Temperature. — The maximum temperature of the arc cannot be measured by direct means and the various estimates, which have been made, range from 3200° C. to 6000° C. Using Wien's law connecting temperature and wave length corresponding to maximum radiated energy, Lummer and Pringsheim found that this wave length was 0.7 μ and the corresponding temperature somewhere between 3750° C. and 4200° C., the latter figure being based upon the assumption of black body radiation.

Sources of Luminosity. — The light of the arc is derived either from the vapor column or from a body heated to incandescence by the vapor column.

In the old carbon electrode arc no special effort was made to utilize the luminosity of the vapor column, the incandescent spot or crater on the positive carbon being relied upon for practically the entire light. For this reason the positive carbon was always placed above the negative in order that the crater might better shed its light downward.

The flame arc, on the other hand, owes the greater part of its luminosity to the vapor column and very little or none to the heat of the positive electrode.

Hissing. — When the crater is surrounded by the hot gases constituting the arc, the arc is silent, but if the crater extends over the tip of the carbon and comes into contact with cool air, a peculiar hissing sound is evolved.

Characteristic of Arcs between Carbon Electrodes. — A peculiarity of the solid carbon arc is that, with any particular length of arc, if the current be increased, the difference of potential across the carbons will decrease. This occurs continuously until a certain point, when in the open arc the voltage drops quite suddenly. If the current is still increased the voltage will again become steady at a much lower value. Between the values before and after the drop, the arc is unstable

Fig. 1

and hisses. The beginning of the hissing period is indicated by the dotted line in Fig. 1, and the hissing continues throughout the lower part of the curve.

The hissing point being absent in inclosed arcs, the curve for such arcs is quite continuous.

Steadying Resistance. — In order to maintain a steady current in an electric circuit it is necessary that any decrease in the voltage across the terminals of the circuit shall produce a decrease in the current. Hence, as the arc characteristic shows an increase of current with decreasing voltage there must be placed in circuit with the arc a resistance great enough to compensate for this tendency, if the arc is to be kept in a stable condition. The method of calculating the resistance required to maintain a stable arc for a given current is as follows:

Let e = generator terminal volts = OE,
v = arc terminal volts,
x = resistance in circuit, exclusive of arc and generator resistance,
i = current in amperes,
then, since $e = v + ix$,

the resistance x must be such that

$$x = \frac{e - v}{i}.$$

On the arc characteristic (Fig. 2) find the point P corresponding to the current i and set off $OE = e$ along the vertical axis. Then join EP and continue EP until it cuts the horizontal axis at X. The resistance x is then equal to $\tan \angle EXO$. If EX cuts the curve not only at P, but at S above P, it would appear that the e.m.f. e could support either of two arcs. The point S, although affording a mathematical solution, is not physically possible, as it would involve an increase of voltage, producing a decrease of current, as may be seen by moving EX upward, parallel to its original position. Hence the arc corresponding to P is the only one possible. If EX cuts the curve not only at P, but at some point below P, say T, the same reasoning shows the arc at P to be unstable, while that at T is stable.

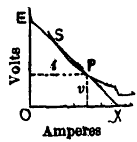

Fig. 2

For any point P, therefore, the arc is stable only if the line EX does not cut the curve below P. Hence, to find the proper value of the resistance x, for a given current i, draw a line tangent to the arc characteristic curve at the point having the abscissa i, then x must be equal to or greater than the tangent of the angle made by this line with the axis of abscissas.

Generator Voltage and Hissing Current. —

Let E = generator voltage,
V = potential difference between carbons just before current is increased to hissing point,
I = maximum amperes which will not produce hissing
D = drop in volts from silent to hissing,
i = rise of current from silent to hissing,

then $$E = V + \frac{I}{i} D \quad \text{or} \quad i = \frac{D}{E - V} I.$$

Thus, if the generator voltage is great compared to the arc voltage, and therefore the steadying resistance great, the rise of current at hissing will be less than when the voltage is small.

Resistance of the Arc.—The relation between the drop of potential across the arc and the current flowing through it depends upon whether the arc is in the steady state corresponding to the current flowing or whether the current has been changed without giving time to the vapor column and electrodes to accommodate themselves to the new strength of current. Let V be the drop of potential across a direct-current arc and A the current flowing. If the current be increased by a small amount dA for so short a time that it produces no effect upon the arc itself, it will be accompanied by a rise in potential difference dV, and the ratio $\frac{dV}{dA}$ will be the resistance of the arc. This may be accomplished experimentally by superimposing upon the direct-current arc a small rapidly-alternating current and measuring the value of the alternating p.d. and current. Unless a very high frequency (about 100,000 cycles) is used, the ratio $\frac{dV}{dA}$ will be negative, due to the fact that the power factor of the arc is not unity for low frequencies and this ratio, therefore, does not represent the resistance (*see Duddell's papers in Bibliography*).

Back Electromotive Force of the Arc.—The product of the direct current of an arc and its resistance, measured as described above, is the ohmic drop in the arc. This is usually less than the actual p.d. by 7 to 15 volts, which represent a back electromotive force. This back electromotive force really consists of two, the larger near the positive electrode, opposing the flow of current, and the smaller near the negative, helping the flow. By varying the direct current carried by the arc, the back e.m.f. is not noticeably affected, but the resistance tends to become infinite for very small currents, and small for large currents. A variation in the length of the arc between solid carbons produces no effect upon the back e.m.f., whereas with cored carbons the back e.m.f. decreases with increase of length. The value of the back e.m.f. depends upon the make of carbons employed. In his experiments which established the existence of a true back e.m.f. in the arc, Duddell used an alternating current of about 1 per cent of the strength of the direct current and having a frequency of 100,000 ~ per second.

ARC AS TELEPHONE RECEIVER. — A direct-current arc may be used as a telephone receiver which can be clearly heard in a quiet room at a distance of 10 or 12 feet. The arrangement of apparatus, which gives the best results, is shown in Fig. 3, which is Duddell's improvement of the H. Simon circuit. In Duddell's experiments AB was a solenoid about 30 cm. long, wound with about 1000 turns of No. 18 D.S.C. wire and having an iron core of about 15 mm. diameter. Six hundred turns of the solenoid were connected to the microphone M and battery B and four hundred to the arc and condenser C.

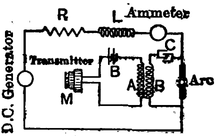

Fig. 3

The arc was between cored carbons of 11 to 13 mm. diameter separated 20 to 30 mm. and took 10 to 12 amperes. The condenser capacity was 2 or 3 microfarads. The resistance R was the usual ballast resistance and the choke coil L served the purpose of confining the telephonic currents to the arc circuit.

ARC AS A TELEPHONE TRANSMITTER. — The arc may be used as a telephone transmitter, but it is unsatisfactory on account of hisses and splits due to the irregularities of the carbons and to the access of air to the crater. The arrangement of circuits is shown in Fig. 4, the apparatus R, L and C being the same as in the receiver circuit.

MUSICAL ARC. — A direct-current arc of suitable length and current between solid carbons will give a musical note, if it be shunted with a con-

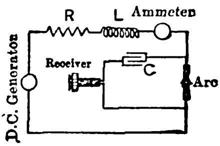

Fig. 4

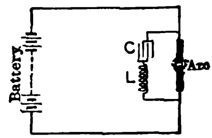

Fig. 5

denser in series with a *choke* coil, as shown in Fig. 5. The pitch corresponds to the periodic time

$$T = 2\pi\sqrt{LC},$$

where

C = capacity of condenser, farads,
L = inductance of choke coil, henrys.

The choke coil must not have an iron core, or the hysteresis and eddy currents will destroy the effect. A closed circuit, such as a ring of wire placed near the inductance coil, has the same effect. Further details of the musical arc are given below.

THE ARC AS A SOURCE OF HIGH-FREQUENCY CURRENT. — The musical arc owes its pitch to the action of the arc in transforming a part of the direct current into alternating current, the frequency of which can be varied between very wide limits by altering the self-inductance and capacity with which it is shunted. The inclosed arc works just as well as the open arc. In some of Duddell's experiments, the *alternating current* through the condenser circuit was as large as 5 amperes. Only condensers suitable for high voltages should be used, as, although the arc p.d. may be quite low, the condenser p.d. rises to several hundred volts. Alternating currents of frequencies of from 500 cycles to 500,000 cycles per second are easily obtainable.

Arcs between solid carbons always work well as converters, while those between cored carbons will not work under any conditions. In fact the general conditions under which the arc works as a converter are that $\frac{dV}{dI}$ must be negative and numerically greater than the resistance of the condenser circuit, exclusive of the condenser itself. The expression $\frac{dV}{dI}$ should be taken as referring to small instantaneous changes of the arc voltage and current.

Fig. 6 shows a means of operating several arcs together so as to obtain a greater output than would be possible with a single arc. Direct current is supplied to the arcs from the mains, through the choking coils L_1 and L_2, the ballast resistance R_1 and R_2 and ammeters A_1 and A_2. Alternating current is delivered by the arcs to the circuit containing the capacity C and inductance L.

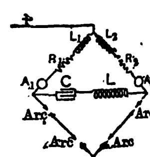

Fig. 6

STEEL BURNING BY MEANS OF ARC. — In addition to its application for welding and electrochemical manufactures (q.v.), the thermal effect of the arc is utilized for burning steel. A recent application of this was made by the contractors of the Pennsylvania Railroad (East River tunnel), who used a carbon

with an asbestos shield, one foot in diameter. The operators worked with asbestos masks and aprons and dark-colored eye glasses. While this sufficed to shield them, other workers some distance away became temporarily blind a few hours after exposure to the glare.

Direct current was used, the carbon electrode being connected to the positive and the steel to be cut to the negative feeders. The current was varied by means of water rheostats, the voltage at the tool varying between 45 and 60 volts. The current varied from 250 to 400 amperes per tool for burning off rivet heads and light section plates and from 600 to 800 amperes for burning plates 4 inches thick. The best results were obtained with 40 volts, 600 amperes and a ½-inch to ¾-inch arc. A fair day's work (8 hours) removed 300 rivet heads, although a record of 350 was reached. In the same time 4 feet 6 inches of 4-inch plate could be burned off. (*H. Japp, Proc. A.S.C.E. 1909, Vol. 35, No. 9, p. 1230.*)

Portable plants, consisting of a gasoline engine driven generator of about 25 kw. capacity, mounted on a truck, are now in use for wrecking buildings. Such an outfit is capable of burning off a 15-inch I-beam in 20 minutes, using the full-rated output of the generator.

The same apparatus is used for filling blowholes in castings. The casting must be heated to a dull red heat before the arc is applied, in order to avoid strains due to local expansion. The heat of the arc may be applied not only as above described, but also by deflecting an arc between two carbons against the casting by means of a magnet. In either case, the filling metal is introduced into the arc and allowed to flow into the blowhole.

[W. A. DEL MAR.]

AUTOMOBILES, ELECTRIC. — (*See also Batteries, Storage, Alkaline Type and Lead Type; Batteries, Storage, Applications of.*) There are two types of electric automobiles, namely the battery car and the "gasoline-electric" car. The former type carries a storage battery from which energy is delivered to the driving motor; the latter type carries no battery but electric energy is supplied to the motor by a small generator which is itself driven by a gasoline engine. The battery car only is discussed in this article. A battery car is commonly referred to as "an electric," regardless of whether it belongs to the passenger or the commercial class.

HISTORICAL DEVELOPMENT. — The first battery-driven automobile in this country was built by Fred M. Kimball in Boston in 1888. This machine had 6 cells of lead storage battery and could travel 10 miles on good roads at an average speed of 5 m.p.h. In 1891 there was exhibited at the Mechanics' Fair in Boston an electric surrey built by the Holzer-Cabot Electric Co. Little more was done in the development of electrics until about 1900, when various makes of electric pleasure cars and trucks began to appear. By 1903 a brisk business in electric vehicles had sprung up. Some of these early machines were failures, due either to poor mechanical construction or to crude operating methods which failed to give reliable service. The only batteries then available were of comparatively heavy types, such as had been used previously in stationary service. The battery situation was soon met by the battery manufacturers in the grid type of pasted lead plate. The Edison battery was first placed on the market in January, 1905. But the electric vehicle business did not assume large proportions until about 1910, when the electric light companies in the large cities began to look toward vehicle charging at night as a possible source of load for increasing the load factors of their systems. With the stimulus of the lighting companies the business began to develop rapidly, there being 37 manufacturers of electric vehicles in this country in 1913. It is estimated that at the close of 1913, there were 25,000 passenger and 10,000 commercial electrics in use in this country. (*A. Williams.*)

APPLICATIONS OF ELECTRICS. — The three types of vehicles which are at present available for urban street haulage are the horse-drawn wagon, the gasoline motor car and the electric battery car. In comparing these three types for use in any given service, the chief factors to be considered are relative speed, distance between stops, length of stops required by the service, expense per vehicle and reliability (i.e., number of days per year upon which the wagon can be depended for operation). The first three of these factors may be determined by trial or by observation.

In considering the matter of speed it should be remembered that with motor cars the wear and tear on the machine increases approximately as the square of the speed, so that the speed should be such as to give minimum cost of service. The last two of the above factors, namely expense and reliability, can be absolutely determined for any set of operating conditions only by several years of use of each type of vehicle. It is possible, however, to closely estimate the "expected" values of expense from the experience of others in similar kinds of work. See section below on *Costs.*

The electric truck has found its widest commercial application in city services where the hauls are of moderate length, say from two to ten miles. For very short hauls where the standing time of the wagon is a large proportion of the working time, so that the work per day of each delivery unit is not largely influenced by the speed of the unit, the horse-drawn wagon can perform the work cheaper than an electric truck. For the so-called "long hauls" the gasoline truck would be expected to work to better advantage than an electric

truck because of higher running speed or greater distance capacity in a day, or both. The rated values of speed and distance on a single battery charge for a representative line of electric trucks are given in Table V below. The effect of hills or poor pavements would be equivalent to a decrease in the rated values of both speed and mileage. Systems of operating in which discharged batteries are exchanged for charged batteries during the day in order to increase the mileage capacity beyond the rated value have been used with signal success in a few instances, but in general such a system is not sufficiently flexible to meet required conditions.

DESIGN. — The necessity of producing cars which would travel at moderate speeds with a low rate of energy consumption has forced the designers of electric automobiles to use equipment which would meet this requirement, even though in some instances less efficient equipment would cost less or might wear longer than that used. Thus tires of low-energy consumption, batteries with large capacity per unit of weight and "non-friction" bearings in transmission and axles are used almost universally. Consequently an electric automobile is essentially a high-grade machine, for any sacrifice in equipment directly influences the operating qualities.

Weight and Speed. — In the design of an electric battery car the two primary features are the total weight and the speed under normal conditions. In special cases a car may be built to meet unusual requirements of distance traveled per charge, in which case either the speed or weight must depart from the limitations of common practice. Any decrease in the total weight of the car will result in an increase in either speed or distance capacity or both; or if the weight is brought back to the original value by the use of additional battery capacity, the speed or distance may be still further increased. This has been one of the chief considerations leading to the universal adoption of lighter batteries, such as the Edison and "thin" pasted lead plate, in place of the "standard" pasted lead plate batteries which were extensively used a few years ago. General practice as regards weight and speed for various types of electric automobiles is indicated in Table I.

TABLE I.—SPEEDS AND WEIGHTS OF ELECTRIC AUTOMOBILES

Class of car or rated capacity of truck	Approximate weight in lb., including empty body	Approximate speed in miles per hour	Weight allowance for body, lb.*
2-passenger runabout	2,200	15 to 25	....
2-passenger Victoria	2,400	15 to 21	....
2-passenger coupé	2,600	15 to 20	....
4-passenger brougham	3,000	14 to 18	....
1,000-lb. truck	3,500	12 to 14	500
2,000-lb. truck	4,500	10 to 12	600
4,000-lb. truck	6,000	8 to 10	800
7,000-lb. truck	8,500	6.5 to 8	1100
10,000-lb. truck	9,500	6 to 7	1400
12,000-lb. truck	11,500	6 to 6.5	1600

* Recommended by Commercial Vehicle Committee of Auto. Chamber of Com. (formerly National Assoc. of Auto. Mfgr., Inc.), March 4, 1912.

Similar data for a representative line of electric trucks are given in Table V below.

Load Efficiency. — By load efficiency of a motor truck is meant the ratio of the load on the machine to the gross weight of the machine, including chassis, body and load. Thus, from the above table, a representative value for the rated load efficiency of a 5-ton capacity electric truck is $\frac{10,000}{10,000 + 9500} = 0.51$. The rated load efficiencies for gasoline trucks of large capacity, 2 tons or more, are practically the same as the values for electric trucks, but small capacity gasoline cars of good design may have a rated load efficiency as high as 30 per cent as compared to about 24 per cent for electric cars with the customary lead battery equipments.

Motors. — Four-pole series motors are now used almost exclusively for electric automobiles. In the majority of cases but a single motor is used on each vehicle. The field coils are usually arranged in two groups which may be connected first in series and then in parallel. All manufacturers do not rate their motors on the same basis, but good practice is indicated by that of the General Electric Co., whose motors will carry their normal rated load continuously with a maximum temperature rise of 65° C. above the surrounding air at 25° C. or will carry 2½ times their rated load for 1 hour with a maximum temperature rise of 75° C. Ratings are based on bench tests, so that when the motor is installed in a car the overload capacity is usually increased due to the improved ventilation. Large overload capacity is necessary to meet severe street and grade conditions, and unusually good commutating characteristics are required.

An automobile motor must also operate satisfactorily over a considerable range in the voltage furnished by the battery in the charged and discharged conditions. The motor speeds which are used with single reduction drives range from 750 to 1000 r.p.m.; the speeds which are used with double reduction drives range from 1000 to 2000 r.p.m.

Number of Motors. — All electric passenger cars and most electric trucks are now being equipped with a single motor. It was formerly common practice to use two motors on the larger trucks on account of flexibility in control, but a single motor is now being used on account of space limitations, saving in weight and better electrical efficiency. The peculiar construction of the Couple-gear (*see below*) equipment requires a departure from this practice. Otherwise, either two or four motor equipment is used now only when unusually high tractive effort is required.

Motor Characteristics. — Along with the tendency during recent years to standardize battery equipments at 40 to 44 lead cells and 60 Edison cells, the tendency among motor manufacturers has been to develop a line of motor frames, for each of which two windings could be provided. Thus an 80- or 85-volt motor is usually installed with a 40- to 44-cell lead battery and a 60-volt motor with a 60-cell Edison battery. The windings are so proportioned that a motor has approximately the same speed and torque at both voltage ratings. This development has made it unnecessary to alter either the motor suspension or the mechanical transmission system in changing a car's battery equipment from lead to Edison or vice versa. 24-, 36- and 48-volt motors can also be obtained.

The characteristic curves for a typical Westinghouse motor with the 60-volt and 80-volt windings are given in Figs. 1A and 1B. The relatively small change in efficiency for overload with the field coils in parallel is noteworthy. The "torque ratio" of this motor, i.e., the ratio of torque at 2½ times rated current to torque at rated current, is approximately 5 with both windings.

The following table gives a partial list of General Electric automobile motors with their normal ratings.

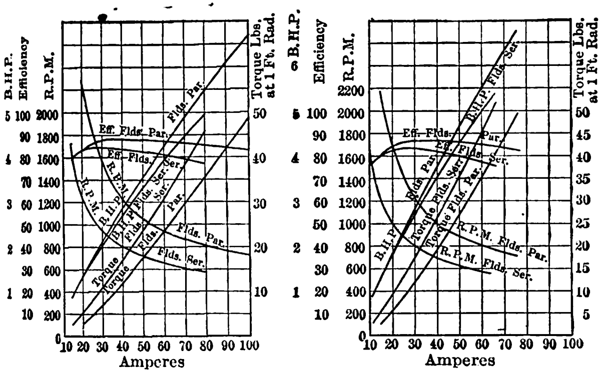

Fig. 1. Characteristic Curves of Typical Automobile Motors

TABLE II.—RATINGS OF G.E. AUTOMOBILE MOTORS

Designation	Rated volts	Rated amperes	Speed, r.p.m.	Approximate weight, lb.
G.E. 1022	60	60	1100	380
G.E. 1022	85	40	1200	380

G.E. 1037	85	20	2000	185

Before recommending motor equipment for automobile service the motor manufacturers usually require that the purchaser submit data upon the weight, speed, battery, wheel dimension, etc., for the car on which the motor is to be used.

Size of Motor Required.—In selecting the size of motor the voltage should be chosen on the basis of 1.9 volts per cell for lead batteries and 1.0 volt per cell for Edison batteries. The average discharge voltages of both types of batteries at their normal rates are higher than these values, but it has been found desirable to install motors on the basis of these values so that at high rates of discharge the terminal voltage may not fall too far below the rated motor voltage.

The current rating of the motor (and also of the battery) should be approximately the value of the current required to drive the car at the rated speed on hard level asphalt. The current input into a vehicle motor when driving a car at constant speed is given by the expression

$$I = \frac{2\,vWr}{E\epsilon},$$

where v = speed of car in miles per hour,
W = total weight of car and load in tons,
r = car resistance in pounds per ton of total car weight,
E = motor terminal voltage,
ϵ = over-all efficiency of motor, controller and transmission.

The value of ϵ at the rated speed is the product of the efficiencies of motor and transmission, usual values falling between 60 and 75 per cent. For value of r see next paragraph.

Car Resistance. — The car resistance depends upon the following conditions: speed, grade, diameter of wheels, load per square inch of tire contact or per inch of tire width, construction and composition of tire, method of attaching tire to wheel rim, and road surface. The effect of speed is to change r in a manner dependent upon the type of tire, the value of r having a minimum usually at a speed between 6 and 10 m.p.h.; air resistance varies approximately as the square of the speed and need not be considered for speeds of less than 20 m.p.h. The effect of up-grades is to increase r by 20 lb. per ton for each per cent grade. The car resistance with pneumatic tires on hard, level asphalt is given by Churchward (*Soc. of Auto. Eng. Handbook, 1913*) as ranging from 15 lb. per ton for special tires designed for electric runabouts up to 35 lb. per ton for the standard type of tire used on gasoline touring cars; the resistance is greatly affected by the air pressure, increasing rapidly as the air pressure is reduced. Churchward also gives the car resistance with solid tires on hard level asphalt as ranging from 18 to 26 lb. per ton. Other tests have shown a car resistance of 30 lb. per ton for a small capacity electric truck equipped with solid tires (*El. W., May 17, 1913, Vol. 61, p. 1040*).

Effect of Road Surface. — Two sets of values of relative car resistance on various level road surfaces as compared to the value on hard, level asphalt are given in the following table. One set of values is given by Churchward in the *Soc. of Auto. Eng. Handbook* (1913), and the other set is based on tests conducted at the Massachusetts Institute of Technology in 1913 (*El. W., May 17, 1913, Vol. 61, p. 1040*).

TABLE III. — RELATIVE VALUES OF CAR RESISTANCE

Road surface	Churchward	M.I.T.
Asphalt, hard	1.0	1.0
Wood block	1.15	1.1
Macadam	1.15 to 3	1.15
Granite block	1.75	2.0
Dirt road	1.1 to 2.0	...
Brick	....	1.4
Snow, packed	....	1.3
Snow, fairly hard, without grips	....	1.7
Snow, fairly hard, with grips	....	1.9
Snow, soft, about 3 in. deep	....	2.1
Sand	20	

Transmission Systems. — The transmission systems between motor and wheel which are in common use may be grouped in two classes, known as the "chain" and the "shaft" or gear drives. A single-speed reduction is used in a few makes of cars, but a double reduction is used on a majority of machines. If the first reduction is made by chain and the second by gear, or vice versa, the transmission system is usually designated according to the means employed for the final reduction; e.g., if the final reduction is accomplished by a chain, the system is referred to as a chain drive although the first reduction may be by gears.

Chain Drive. — With chain drive the motor is mounted transversely and a double-speed reduction is used almost without exception. The connection between motor and countershaft is usually by silent chain (Morse or Reynold type, see article on *Chains and Chain Drive*), although spur and herringbone gears are also used; see article on *Gears and Gearing*. The final drive is usually by roller chain, either (*a*) between countershaft and differential in the rear axle, or (*b*) between countershaft and a sprocket on each of the rear wheels. Chain-driven passenger cars are usually equipped with (*a*) and chain-driven commercial cars with (*b*). The chain method of drive possesses the advantages of low first cost and ease of adjustment; its disadvantages are noise, rapid wear due to collection of dirt unless properly housed, poor efficiency when not properly adjusted, and unequal wear on the two sides of the car. The chain drive has been losing favor during recent years among both designers and operators.

Shaft or Gear Drive. — With shaft drive the motor is usually mounted lengthwise of the car, and either a single- or double-speed reduction is used. For single reduction both bevel and worm gears are used as the connection between propeller shaft and differential in the rear axle. For double reduction the motor is usually connected to the propeller shaft by spur gear, herringbone gear or silent chain, and the propeller shaft is connected to the differential by a bevel gear. The propeller shaft is usually fitted with universal joints. The shaft drive has become very popular in passenger cars because it runs quieter than chain drive, and because it can be easily protected from dirt by housing. The shaft drive has the disadvantage of greater weight below the springs than in the case of the chain drive, which tends to increase the wear on tires.

Worm Drive. — There has recently been a decided tendency among designers of passenger cars and light trucks to use the single-reduction worm gear instead of the double-reduction bevel or chain arrangements, the advantages claimed for the worm being better transmission efficiency and less trouble from adjustment.

Walker Balanced Gear. — In the trucks built by the Walker Vehicle Co. the motor is built into the rear axle, which is made hollow and of a sufficient diameter to contain the motor. The armature shaft is also hollow, so that the drive shafts may extend through from the sockets of the differential to the center of each rear wheel. The wheels are driven by a spur-gear reduction mounted inside the wheels. The wheels have steel-plate sides instead of spokes, so that the gears may run in oil and are thoroughly protected from dirt.

Couple-Gear Wheel. — A device built by the Couple-Gear Freight Wheel Co. has the electric motor mounted inside the wheel. The motor armature carries a pinion on either end which engages with a gear rack on either side of the wheel. The sides of the wheels are dished steel plates. These wheels are being used on both front-wheel-drive and four-wheel-drive machines Being located in the wheels, they do not interfere with the use of the ordinary steering knuckle arrangement.

"Differential" or Differential Gear. — All cars equipped with a single motor have a differential gear to permit the transmission of power from motor to both wheels and yet permit the wheels to revolve at different speeds. The working parts of the bevel-gear type of differential are indicated in Fig. 2. The large gear *D* is driven by the pinion *S* on the propeller shaft. Mounted within *D* and carried on spindles in the plane of *D* are four small bevel pinions *P* (only two are shown in the figure). Bevel gears *G* and *G′*, attached to the ends of the axle shafts, mesh with the pinions *P*. Thus if *G* is stationary or presents greater resistance than *G′*, the pinions *P* will roll over the surface of *G* and also upon their own spindles, turning *G′*. If the resistance of both wheels is the same, the pinions *P* will not revolve on their spindles and the gears *G* and *G′* will be revolved at the same speed. (*Description abstracted from the Electric Vehicle Handbook, by Cushing and Smith.*)

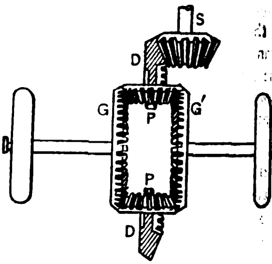

Fig. 2.

Efficiency of Transmission. — (*See also article on Gears and Gearing.*) Beaumont gives the following figures on the transmission efficiency of different types of automobile mechanisms.

Source of loss of power	Efficiency, per cent
One chain, and one and one-half pairs of bearings	89.5
One set of gears, two pairs of bearings	82.0
One set of gears, equivalent of two chains, three pairs of bearings	74.0
Two sets of gears, four pairs of bearings	70.0

The following figures, given by F. Burgess (*Trans. Soc. Auto. Eng., 1912, Vol. 7, Part 2, p. 196*), are the results of an efficiency test of a straight type worm and worm gear for rear-axle drive of electric automobiles. The worm gear was made of phosphor bronze and had 39 teeth; the worm was made of case-hardened steel and had 4 threads.

R.p.m. of worm	Temperature of worm gear, °F.	Input, trans. dyn., h.p.	Output, brake h.p.	Efficiency, per cent
1393	74	1.64	1.03	61.2
1416	86	3.41	3.17	93.2
1370	90	5.48	5.13	93.7
1389	94	6.72	6.24	93.0
1400	108	9.43	8.5	90.2

Batteries. — There are three types of batteries in general use in electric vehicles, namely, the pasted lead, the "Iron-clad" lead, and the Edison. The performance characteristic (except life) of the first two are identical and are described in the article on *Batteries, Storage, Lead Type;* the characteristics of the Edison battery are described in the article on

Type. The desirable characteristics of a battery for vehicle service are given in the article on *Batteries, Storage, Applications of.*

Number of Cells; Number of Plates. — Practice among electric automobile manufacturers is rapidly becoming standardized upon the installation of 40, 42 or 44 cells of lead battery and 60 cells of Edison battery in both passenger and commercial classes of cars, as these numbers permit of charging from a 115-volt circuit with minimum loss in the rheostat. The exceptions are chiefly in the lower-priced pleasure cars in which from 24 to 38 lead cells are sometimes used, and the small capacity delivery wagons in which 48 Edison cells are commonly used. A 24-volt battery is usually used on industrial trucks. For a given watt-hour capacity a battery of a small number of cells is cheaper to buy and maintain than one of a large number of cells, but is more expensive to charge from constant-potential d-c. mains on account of rheostat losses.

As pointed out above the rated current output of a vehicle battery for 4 hours should not be exceeded by the current required to drive the car at rated speed on hard, level asphalt (*see section above on Size of Motor*). Thus when the current under these normal conditions is known, the number of plates per cell can be determined from a knowledge of the discharge rates of the various types of plates which are under consideration. For A-type Edison batteries the normal (5-hr. rate) is 7.5 amp. per positive plate; conservative designers use this rate in applying batteries rather than the value of 9.5 amp. which could be obtained for 4 hours. The discharge rates per positive plate of 5¾ by 8⅝ in. for 4 hours and for the so-called "normal" times of discharge for the types of vehicle batteries made by the Electric Storage Battery Co. are given in the accompanying table.

Type of plate	"Normal" discharge		Amperes per positive plate discharged during 4 hr.
	Time, hours	Amperes per positive plate	
Exide	4	7	7
Hycap	5	5.5	6.5
Thin	6	4.25	5.8
Iron-clad	4.5	7	7.6

It will be noted that the above rule of installing a battery whose 4-hour discharge rate is approximately equal to the current required for running at rated speed under good street conditions will furnish a minimum practicable battery capacity, and that this capacity may have to be increased materially in order that the car may meet the necessary mileage requirements when operating on grades or poor roads. There is a tendency among electric car manufacturers to recommend battery equipment for given conditions which is much more liberal than they recommended a few years ago.

Construction of Battery Box. — In passenger cars a tight wood-lined compartment is usually supplied for carrying the battery. In commercial cars the battery compartment is also wood lined, and provision is commonly made for ventilation to facilitate charging in warm weather. The details of a typical underslung battery box are shown in Fig. 3. With this construction strips may be laid in the spaces between the floor boards in order to make the compartment entirely inclosed, as is frequently desirable in cold weather. A

tight covering should be provided with an underslung battery box to prevent dirt and water falling upon the battery from the floor of the car.

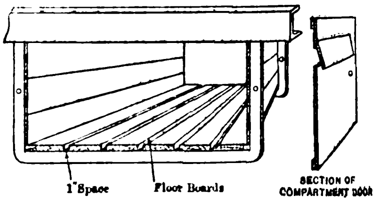

Fig. 3. Typical Underslung Battery Box

Controllers.—Controllers are usually of the drum type with two running positions, known as the "field-series" and the "field-parallel" positions. The motor field coils are arranged in two groups for connection either in series or in parallel. The cells of the battery are connected permanently in series. In starting, either 2 or 3 resistance notches are used before the "field-series" notch is reached. A shunt on the fields is frequently used between the "field-series" and the "field-parallel" notches. For normal full-speed running the two groups of field coils are in parallel. An emergency speed is obtained by shunting a resistance around the fields when connected in parallel. It was formerly customary to split the battery into two groups which could be operated in series-parallel in order to obtain 4 economical running speeds, but trouble was experienced from the unequal discharge of the two halves of the battery. In the magnetic type of control which is used to some extent in passenger cars the changes in connection are affected by relays operated by an auxiliary electric circuit. Some forms of regenerative control have been tried with only moderate success, although in hilly localities regenerative control may be desirable on account of protecting the mechanical brakes.

Tires.—Tires for use on electric automobiles are generally more resilient than the standard types of tires commonly used on gasoline automobiles. "High efficiency" or special electric tires, both solid and pneumatic, have been developed by most of the tire manufacturers in response to a demand by the operators of electric cars for tires with low consumption of energy. Standard types of tires may consume as much as 100 per cent more energy than the special electric tires. Experience has shown that the smooth starting characteristic of an electric motor produces much less abrasion than the uneven acceleration with a gasoline motor, so that the rubber compounds in tires for electric cars are usually softer than the compounds in tires for gasoline cars and yet the lives of both types in point of distances traveled are approximately the same. Electric pneumatic tires are usually of the cord type; i.e., the "fabric" consists of parallel strands of cotton impregnated with rubber gum. Some types of solid electric tires, such as the Motz, have the sides undercut at intervals to allow for the "flow" of the rubber when under compression.

Carrying Capacities of Tires.—In general a tire of small transverse tread will consume less energy than a tire of the same compound with large tread when operating on a smooth, hard surface; also, a large wheel diameter gives less energy consumption than a small one as well as improving the riding qualities on uneven surfaces. The Society of Automobile Engineers have recommended the use of 32-, 36- and 40-in. tires as standard practice. (*See Trans. Soc. Auto. Eng., 1914.*) But in selecting tire equipment it should be remembered that there is a limit to the load which any size of tire will stand without permanent injury by disintegration. The maximum carrying capacities per wheel at present (1914) recommended by the B. F. Goodrich Co., are given in the following table, as are also the recommended inflation pressures for pneu-

matic tires of the fabric type; the recommended inflation pressures for cord tires are approximately 80 per cent of the values in the table.

TABLE IV. — MAXIMUM CARRYING CAPACITIES OF TIRES

Size of tire, inches	Maximum load, pounds per wheel				Recommended inflation pressure, lb. per sq. in.
	Solid		Pneumatic*		
	Single	Dual	Rear wheel	Front wheel	
2	500	......	....	....	...
2½	750	1,950	....	....	...
3	950	2,475	375	450	55
3½	1375	3,675	500	600	60
4	1750	5,000	750	900	70
5	2000	6,000	1100	1300	90
6	3000	8,000	....	....	110
7	4000	10,000	....	....	...

* The allowable load per wheel for a given width of tire increases slightly with the wheel diameter. The sizes quoted in the table are 32 by 3, 32 by 3½, 36 by 4, and 36 by 5 in.

Examples of Commercial Car Design. — The following table gives data from the standard specifications of a number of the electric trucks made by the General Vehicle Co.

TABLE V. — DATA ON "G.V." ELECTRICS

PERFORMANCE; ENERGY CONSUMPTION.—The energy consumed by an electric automobile will depend very largely upon the care of the driver in coasting up to stops instead of braking directly from full speed; other im-

portant factors in determining the energy consumption are efficiencies of battery and driving mechanism, tire equipment, nature of roads and grades, number of stops and miles per day, etc. However, for a car which is operated under similar conditions day after day, the energy consumption per mile should be reasonably uniform, so that any considerable increase in energy consumption may indicate either careless driving or poorly adjusted mechanism, as for instance a dragging brake. Table VI gives a series of approximate values for energy consumption per mile which are based upon a large number of reports upon the operation of electric cars in large cities; these reports were collected in connection with the Vehicle Research study conducted during 1912 to 1914 by the Electric Research Laboratory of the Massachusetts Institute of Technology. These figures are representative of experience with modern types of cars under average city conditions; the consumption for a given set of conditions may vary from the figures by as much as 20 per cent, either above or below.

TABLE VI.—ENERGY CONSUMPTION IN KILOWATT-HOURS PER MILE

Type of car	Lead battery	Edison battery
2-passenger	300	400
1,000-pounds	550	750
2,000-pounds	650	900
4,000-pounds	830	1150
7,000-pounds	1100	....
10,000-pounds	1400	....

Garage Load Curves.—Fig. 4 shows a typical daily load curve for a public garage handling 75 electric passenger cars; Fig. 5 shows a similar typical daily curve for the private garage of a large department store (*see paper by E. E. Witherby, Proc. N. E. L. A., 1913*). The "off-peak" character of the electric vehicle load is indicated by these curves. In order to attract such off-peak load most light and power companies are now offering special rates for vehicle charging, frequently with the provision that no charging shall be done during the time of the power company's daily peak load.

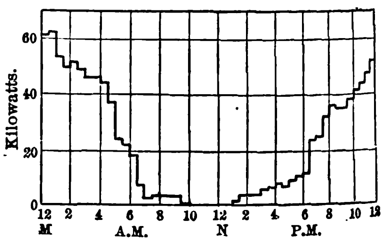

Fig. 4. Daily Load Curves of a Public Garage Handling Passenger Cars

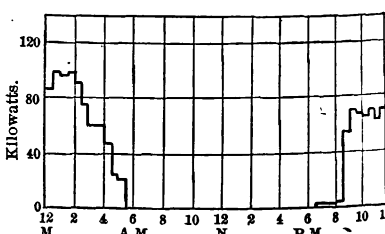

Fig. 5. Daily Load Curves of a Private Garage Handling Trucks

OPERATION.—In the operation of electric automobiles particular attention should be paid to the proper care of the storage batteries. The battery manufacturing companies issue complete instructions for the proper handling of their cells. The

manufacturers of the battery, as well as the manufacturers of the car, are usually ready to confer with the operator of a car to the end that he may obtain satisfactory service from his machine. They should be consulted on the first indication of trouble in their respective portions of the equipment, should the cause of the trouble not be understood.

The following points upon the care and operation of electric cars should be observed:

1. A battery must always be charged with direct current and in the right direction.
2. Never bring an exposed flame near a battery while charging or immediately afterwards.
3. Do not allow the battery temperature to exceed 110° F.
4. Keep the cells filled to the proper level by adding distilled water only. Never put acid in an Edison battery under any circumstances.
5. Keep the outside of the cells free from foreign substances, both solid and liquid.
6. For boosting a lead battery during a specified short period, the maximum current rate I which may be used without reaching the gassing point is the quotient of the ampere-hours Q previously discharged (read from ampere-hour meter), divided by 1 plus the hours H available for boosting, viz., $I = \frac{Q}{1 + H}$.
7. The mechanism of a car should be inspected carefully at least once in two weeks.
8. A car should be entirely overhauled at least once each year, in order that worn parts may be located and replaced.

COSTS. — The initial cost of passenger electrics depends so largely upon the character of body and fittings that it is impossible to quote any but the most general figures; prices range from $1500 to $5000, the most popular cars selling at from $2500 to $3000. It is likewise impossible to quote definite figures on the cost of operating pleasure cars; prices for electricity for private charging vary from about 3 cents per kw-hr. upward; the cost of storage in public garages ranges from $15 to $30 per month, plus a charge for electricity at from 4 cents per kw-hr. upward.

The initial cost of commercial electrics ranges from about 40 cents per pound for large trucks to 55 cents per pound for light cars, based upon usual equipment of solid tires, lead batteries and express or stake bodies. (*For typical weights see Tables I and V.*) Special equipment such as winches or dumping bodies is additional. The operating expense will vary widely for different conditions, so that it is impossible to predetermine the total cost of operating a truck of a given rating without knowing the requirements of the service, the nature of the roads, and the general method of handling and caring for the car. The data in the following table are deduced from estimates by Pender and Thomson given in *Vehicle Research Bulletin No. 3*, issued in 1913 by the Massachusetts Institute of Technology. The figures are based upon reports of the operation of a large number of cars during from 1 to 4 years in city trucking and delivery services.

TABLE VII. — COST OF OPERATING ELECTRIC TRUCKS

Rated load capacity, lb.	**1000**	**4000**	**7000**	**10,000**
Miles per year considered	10,500	9100	8850	8000
Cents per mile for:				
Tires, repairs and battery*	6.8	8.3	11.2	14.3
Electricity at 3 c per kw-hr	1.5	2.2	3.0	3.6
Dollars per year for:				
Garage and lubricants	215	235	255	285
Driver and helper	1,000	1140	1210	1210
Depreciation, interest and insurance	380	464	532	685
Total annual expense, dollars	2,455	2794	3252	3610

* Pasted plate lead battery.

AUTO-TRANSFORMERS AND COMPENSATORS. — (*See also Starters, Motor; Transformers.*) An auto-transformer or single-circuit transformer, also called a "compensator," consists of a transformer having the usual iron core but only one electrical circuit instead of two. This circuit is tapped at various points as shown in Fig. 1, and the primary and secondary circuits, while independent outside the transformer, unite in the same winding in the transformer. If an alternating voltage is impressed across the points *ab*, a magnetizing current will flow in the winding setting up an alternating flux which will link every turn and induce therein an alternating voltage. The voltage between any two taps, as *ac*, is proportional to the number of turns between the taps; thus any ratio of voltages may be obtained. If the secondary *ac* is loaded a current will flow in the primary and the primary and secondary currents will flow in the two parts of the winding as indicated in the figure.

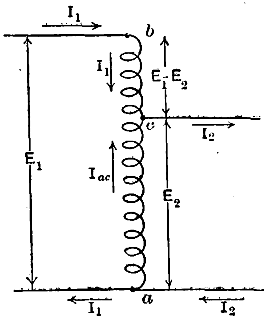

Fig. 1. Auto-transformer

VOLTAGE AND CURRENT RELATIONS. — Let N_1 be the total number of turns between a and b, N_2 the turns between a and c, E_1 the voltage across the terminals a and b and E_2 the voltage across the terminals a and c. Then, neglecting the resistance and reactance of the winding,

$$E_2 = \frac{N_2}{N_1} E_1.$$

Let I_1 be the current entering the terminal b, I_2 the current in the *external* circuit connecting a and c, and I_{ac} the current *in the transformer winding* between a and c. Then, neglecting the resistance and reactance of the winding and the magnetizing current,

$$I_2 = \frac{N_1}{N_2} I_1,$$

$$I_{ac} = I_2 - I_1 = \frac{N_1 - N_2}{N_2} I_1.$$

The current in the turns between b and c is

$$I_{bc} = I_1.$$

Auto-transformer Versus the Two-circuit Transformer.—For $N_2 = \frac{1}{2} N_1$ the current in the turns between a and c would be just equal, neglecting the exciting current, to the current in the turns from b to c (but opposite in direction). Consequently for a 2 to 1 transformation but one winding of an ordinary two-circuit transformer could be used, provided a tap was available at the middle point of this winding, and the rated output of the transformer could be obtained without the current in this winding exceeding its rated value. Since under these conditions there would be no current in the second winding, the heating of the transformer would be less than it would be were the transformer used as an ordinary two-circuit transformer, and therefore a greater output could be obtained without exceeding the nominal temperature rise.

In general, for the same power input into the connected load an auto-transformer requires but $\frac{E_1 - E_2}{E_1}$ of the copper required for a two-circuit transformer,

where E_1 is the high-tension and E_2 the low-tension voltage. The higher the ratio of transformation the less the saving in copper. There is also a serious objection to an auto-transformer of high ratio of transformation, in that an accidental ground on the high-tension lead, *b* in Fig. 1, would establish a high voltage between the low-tension leads and the ground, which may cause a dangerous shock to a person touching either low-tension lead or may cause other damage. This may be partially prevented by grounding the common point of the high- and low-tension circuits, the point *a* in Fig. 1, in which case an accidental ground on the high-tension side would produce a short-circuit, which would open the circuit breaker in the primary circuit, *provided the resistance between the two grounds is low and the circuit breaker operates properly.* These two provisions, however, may not always be realized even though reasonable care is taken, and it is therefore not considered good practice to use an auto-transformer of high ratio of transformation, except in special cases where economy of space is an important factor and danger from shock can be guarded against, e.g., on a-c. locomotives.

RATING OF AN AUTO-TRANSFORMER.—In commercial practice the rating of an auto-transformer in volt-amperes is taken equal to the difference between the high- and low-tension voltages multiplied by the rated current in that part of the winding, *bc* in Fig. 1, across which this voltage exists. The capacity of an auto-transformer for a given work bears to the capacity of a two-circuit transformer for the same purpose the ratio $\frac{E_1 - E_2}{E_1}$. For example, to step down the voltage of the supply mains from 500 to 400 volts and supply a load of 100 kv-a. would require an auto-transformer having a rating of $\frac{500 - 400}{500} \times 100 = 20$ kv-a. as against a two-circuit transformer having a rating of 100 kv-a. The weight, dimensions and cost of an auto-transformer are very nearly the same as for an ordinary two-circuit transformer having the same voltage and kv-a. rating.

APPLICATIONS.—Auto-transformers are used chiefly where the required change in voltage is small, e.g., for motor starters (*see Starters, Motor*), and for balancing the voltage between two or more circuits. The smaller the ratio of transformation the greater is the gain in cost and efficiency resulting from the use of an auto-transformer instead of a two-circuit transformer. Auto-transformers are also used to provide a neutral for the Edison three-wire system; see *Distribution Circuits*. In single-phase railway work single-phase auto-transformers are used on the locomotives for transforming the trolley voltage (from 3000 to 6000 volts) to the motor voltage (about 500). This is a rather high ratio of transformation for an auto-transformer, but as the saving in weight is very important and as one terminal is grounded, it has proven satisfactory for this service; see *Locomotives, Electric.*

DESIGN.—The design of an auto-transformer is quite similar to that of a two-circuit transformer (q.v.) and the leakage reactance is calculated in the same way. For low-leakage reactance the primary and secondary coils must not be entirely separated, but each must be divided into sections and intermixed to as great an extent as possible. Having found the magnetizing current, core-loss resistance and reactance in the usual manner, the calculations follow the same methods as for power transformers. In general, the efficiency at unity power factor is given by the equation

$$\text{Efficiency} = \frac{E_2 I_2}{E_2 I_2 + (r_1 - r_2) I_1^2 + r_2 (I_2 - I_1)^2 + \text{core-loss}},$$

where r_1 is the total resistance of the winding measured between the high-tension terminals and r_2 the resistance measured between the low-tension terminals. The efficiency is better than that of a two-circuit transformer of the same kv-a. rating.

TESTS, SPECIFICATIONS, ETC. — See *Transformers*.

DIMENSIONS, WEIGHT AND COSTS. — For the same kv-a. rating the dimensions, weight and cost are very nearly the same for auto-transformers as for ordinary two-circuit transformers; see *Transformers*.

BALANCES, CURRENT. — (*See also Ammeters; Electrodynamometers.*) The Kelvin balance consists of a system of two coils mounted one at each end of a rigid beam and free to move between two pairs of field coils. The balance may be used as an ammeter, voltmeter or wattmeter. It may be used for either a-c. or d-c. measurements, but for d-c. work it has been practically superseded by laboratory standard voltmeters. For a-c. work it is used only as a laboratory standard for calibrating other instruments.

A current balance when carefully constructed may be used for the absolute measurement of electric current, since the force of attraction between the coils can be calculated in terms of their dimensions and the current flowing. It has been successfully used to determine in absolute measure the electrochemical constant or Faraday (*see Electrochemistry, Principles of*).

Principle of Operation. — The principle of the current balance is similar to that of the electrodynamometer. The connections for current measurements are shown in Fig. 1. The current passes through all the coils in series and as a result of the action of the magnetic fields, the left-hand end of the beam is depressed and the right-hand end is elevated. The beam on which the middle coils are mounted has an index pointer and carries a weight that may be slid along a scale on the beam. With no current on and the sliding weight at zero on the scale, a counter weight on the swinging system is so adjusted that the index pointer on the system is opposite a fixed mark and the system is balanced.

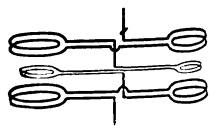

Fig. 1. Connections for Current Balances

Passing current through this system destroys the balance which is restored by sliding the weight along the beam. Since the torque exerted on the moving system is proportional to the square of the current, the current flowing will be proportional to the square root of the distance through which the weight has to be moved to balance the beam.

In the case of the wattmeter the current passes through the fixed coils, while the coils on the moving system serve as the potential coils. In this case the power is directly proportional to the distance through which the weight has to be moved to balance the system.

Range and Cost. — Kelvin balances are built in 5 standard sizes. The useful range and approximate cost of each instrument is given below.

Type	Range, amperes	Approx. cost
Centi-ampere	0.025–1	$150
Deci-ampere	0.25–10	150
Deca-ampere	5–100	150
Hekto-ampere	30–600	150
Kilo-ampere	100–2500	250

[H. Pender and H. R. Ranken.]

BATTERIES, PRIMARY. — (*See also Cells, Standard; Electrochemistry, Principles of.*) A primary battery or cell is a device for the *direct* transformation of chemical energy into electrical energy. For convenience of treatment primary batteries may be classified as wet batteries, dry batteries and standard cells. The latter are treated in the article on *Cells, Standard.* The wet battery at one time was largely used in laboratory testing, for telephones, bells and other devices requiring small amounts of energy. In recent years it has been largely supplanted by the dry battery and small storage battery cells (*see Batteries, Storage*). Dry batteries are now (1913) used, in this country alone, to the extent of some 50,000,000 a year, chiefly for gas-engine ignition and telephone work (*see Gas Engines and Telephone Instruments*).

Poles and Electrodes. — The pole or terminal of a battery which is at the *higher* potential is called the *positive* pole or terminal, the other pole being called the negative pole or terminal. The negative pole is the anode or *positive electrode* or plate and the positive pole is the cathode or *negative electrode* or plate. For example, in a copper-acid-zinc battery the copper is the positive pole but the negative electrode or plate.

THEORY OF PRIMARY BATTERIES. — The modern theory of primary batteries is fully discussed in the article on *Electrochemistry, Principles of.* Only one or two points of practical moment will be mentioned here.

Electromotive Force. — A battery consists essentially of two metallic conductors or poles dipping into an electrolyte. Copper or carbon is commonly employed for the positive pole and zinc for the negative pole. The electrolyte may be sulphuric or nitric acid or sal-ammoniac, caustic soda or other salt. For a battery made of given materials the open-circuit e.m.f. is always the same provided the temperature, degree of concentration of the electrolyte and the purity of the materials are the same. The terminal e.m.f. or potential difference (p.d.) on closed circuit is always less than the open-circuit e.m.f. due (1) to the internal resistance of the battery, (2) to the polarization of the battery and (3) to the exhaustion of the battery.

Internal Resistance. — Let E be the initial open-circuit e.m.f. of the cell and V be the p.d. across its terminals, when it is supplying a given current I, then the "apparent" internal resistance of the cell is

$$r = \frac{E - V}{I}.$$

This is not the true resistance of the cell, for its net e.m.f. when a current I is being drawn from it is less than the initial open-circuit e.m.f. due to polarization (*see below*) and partial exhaustion. If, however, after measuring the p.d. on closed circuit the current is interrupted and the open-circuit e.m.f., say E', be measured *immediately* (i.e., before the polarized condition of the cell has had time to change) then the true internal resistance of the cell is

$$r' = \frac{E' - V}{I}.$$

Polarization. Depolarizers. — Polarization is the name applied to the changes produced in the relative concentrations of the electrolyte at the two poles of a cell or to the production at the poles of new chemical substances (such as hydrogen) as a result of the flow of current through it. A depolarizer is any substance which when placed in the electrolyte or on the poles of the cell will partially or wholly prevent these changes. Polarization always tends to reduce the effective e.m.f. of the cell. When a cell which has been polarized is open-circuited, the relative changes in concentration gradually disappear, due

to diffusion, and any new substances formed also tend to diffuse uniformly through the electrolyte, with the result that the open-circuit e.m.f. returns in time to nearly its original value, provided the active materials are not exhausted.

The chief cause of polarization in a cell is the formation of hydrogen gas at the positive pole or to the transfer of the metal from the negative pole to the positive pole. The depolarizer is usually an oxidizing agent which reduces the hydrogen or metal liberated at the positive pole to a form readily soluble in the electrolyte and thereby prevents its accumulation at the positive plate. This is the principle on which depends the depolarizing action of the various metallic oxides, such as manganese peroxide or cupric oxide. The same result may be obtained by surrounding the positive pole by a solution of a salt of itself which has the same acid radical as the electrolyte surrounding the negative pole, but which is less soluble, the two solutions being kept practically separated by a porous cup which renders the diffusion of one into the other very slow.

TYPICAL WET BATTERIES. — Numerous forms of wet batteries have been used; only some of the more common forms can be described here. The materials used and the e.m.f. developed and approximate range of internal resistance are listed in the following table.

TYPICAL WET BATTERIES

	Daniell	**Gravity**	**Bunsen**	**Chromic acid**	**Edison-Lalande**	**Leclanché type**
Positive pole....	Cu	Cu (b)	C	C	C	C
Negative pole....	Zn (a)	Zn (a)	Zn (a)	Zn (a)	Zn (a)	Zn
Electrolyte....	H_2SO_4 or $ZnSO_4$	$ZnSO_4$ or $MgSO_4$	H_2SO_4	H_2SO_4 or NaCl	KOH or NaOH	MnO_2
Depolarizer......	$CuSO_4$	$CuSO_4$	HNO_3	CrO_3	CuO	NH_4Cl
Separator........	Porous pot	None	Porous pot	With or without pot	None	With or without pot
E.m.f., volts.....	1.07 to 1.14	1	1.9–1.95	2	0.75	1.5
Resistance, ohms	0.3 to 30	0.1 to 6	Low	0.5 to 4	0.02 to 0.1	1 to 5

a. Amalgamated. b. In the Krüger cell copper-plated lead is used.

Daniell Cell (Fig. 1). — A typical form of this cell is shown in Fig. 1. Other forms, differing in certain details, are Muirheads cell, the Siemens & Halske Daniell cell, Minotto's cell (which may also be classed as a gravity cell, *see below*), etc. J is a glass or glazed earthenware jar containing a concentrated solution of copper sulphate, P is a porous pot containing dilute sulphuric acid (about 10 per cent by volume) or zinc sulphate solution or both, C is the positive copper pole and Z the negative zinc pole which is usually amalgamated. The chemical reaction which takes place may be represented by the formula

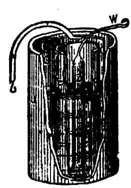

Fig. 1. Porous Pot Daniell Cell

$$Zn + CuSO_4 = Cu + ZnSO_4$$

A current of 1 ampere for 1 hour deposits 1.186 grams of copper and liberates 1.219 grams of zinc. Hence

0.042 oz. copper is deposited per ampere-hour,
0.043 oz. zinc is used up per ampere-hour,
0.164 oz. copper sulphate crystals are used up per ampere-hour,
0.106 oz. zinc sulphate is formed per ampere-hour.

The latter when crystallized out will form 0.189 oz. zinc sulphate crystals. These figures do not include any loss of zinc due to local action, which may amount to 10 per cent or more.

E.M.F. of Daniell Cell.—The e.m.f. of a Daniell cell varies from about 1.07 volts to 1.14 volts, depending on the density of the copper sulphate solution and on the amount of zinc sulphate present in the dilute sulphuric acid. The cell has its highest e.m.f. at the start when the sulphate of copper solution is saturated and no sulphate of zinc has formed. Hence, in order that the e.m.f. shall remain more nearly constant, it is better to start with *both solutions saturated*. The resistance of the cell will be higher and its e.m.f. lower than when dilute sulphuric acid is used, but this lower value of about 1.10 volts will be maintained nearly constant while the cell is sending a current.

Internal Resistance of Daniell Cell.—This depends not only upon the dimensions of the cell but also upon the porosity of the pot or other separating medium. The type of cell shown in Fig. 1, having a pot 7 inches high which is quite porous, has an internal resistance of about 0.3 ohm. The resistance of the Siemens type of Daniell cell is from 10 to 15 ohms, and the resistance of Minotto's modification of the Daniell cell, in which a layer of sawdust or sand is used in place of the porous cup, may be as high as 30 ohms.

The resistance of a Daniell cell, like that of liquids generally, *diminishes* with *increase* of temperature.

Local Action.—Impurities in the zinc form with the zinc small short-circuited voltaic cells, resulting in a wasting away of the zinc without producing a current in the external circuit. This can be largely prevented by amalgamating the zinc, i.e., coating it with mercury, which is readily done by thoroughly cleaning the zinc by dipping it into dilute sulphuric acid and then rubbing mercury over its surface. In the Daniell cell metallic copper also forms in the pores of the porous cup where the zinc touches it; this can be prevented by covering with paraffin those portions of the cup which may come into contact with the zinc.

Care of Daniell Cells.—The type of cell shown in Fig. 1 must be taken to pieces when not in use. If it has to be put to one side for only an hour or two, it will be sufficient to lift the porous pot with the contained zinc rod bodily out of the cell, and to place it in another empty jar, or stand it in a dish while out of use.

Gravity Battery (Fig. 2).—The principle of this cell is the same as that of the Daniell cell, except that no porous pot is used, the copper sulphate and zinc sulphate being maintained separate by gravity. There are various modifications in the form of construction, known as the Meidinger cell, Calland cell, Kelvin tray battery, Krüger cell, etc. The gravity cell is still used in telegraph and telephone work.

The copper electrode is placed at the bottom of the cell, and is then covered with copper sulphate crystals. The zinc electrode is then put in place and the jar either filled with dilute zinc sulphate or with dilute sulphuric acid. When first set up the internal resistance is high, but if the cell is short-circuited for a considerable time the resistance is reduced due to the formation of zinc sulphate. To prevent evaporation the solution is covered with a layer of mineral oil.

Care of Gravity Battery. — The resistance of the cell increases rapidly with decrease of temperature; it should therefore be kept at a reasonably high temperature, say 70° F. A gravity cell must, of course, not be moved about, or if moved great care must be taken to avoid the two liquids being mixed together. To prevent the copper sulphate wandering to the zinc plate, it is well to allow the cell to send a weak current through an external circuit of considerable resistance even when the cell is not in ordinary use. The electrolyte should be renewed when the blue sulphate solution turns brown. The line of separation between the copper and zinc sulphates, or the "blue line," should be about halfway between the two electrodes.

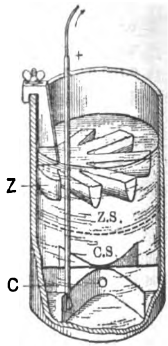

Fig. 2. Gravity Daniell Cell

Bunsen Cell. — In the Bunsen cell a zinc plate is placed in dilute sulphuric acid, as in the Daniell, but the copper plate is replaced by one of carbon and the copper sulphate solution by strong nitric acid, which is generally said to act as the depolarizer. The Grove cell differs from the Bunsen only in the use of platinum in place of carbon. Both cells give a high e.m.f., from 1.9 to 1.95 volts, and have low internal resistances, so they may be used for producing fairly large currents. When working the cells give off dark brown fumes of nitric peroxide, NO_2, and should be placed in the open air or under a chimney.

The chemical reaction which takes place may be represented by the formula $Zn + H_2SO_4 + 2\,HNO_3 = ZnSO_4 + 2\,H_2O + 2\,NO_2$.

Care of Bunsen Battery. — A Bunsen or Grove battery must be taken to pieces at the end of each day's use, since the mixing of the liquids through the walls of the very porous cup used to separate them would render the battery practically useless the next day. The porous pots should be placed in water after use, so that all the zinc sulphate solution may be dissolved out of the pores of the earthenware, for, otherwise, when the pots are dried the zinc sulphate solution will crystallize in the pores and cause the pots to fall to pieces.

Chromic Acid Cell (Fig. 3). — The chromic acid or potassium bichromate cell was devised by Poggendorff. In the original type of cell no porous pot was employed. In the Fuller cell, shown in Fig. 3, a porous pot is used. The depolarizer used is chromium peroxide, popularly called chromic acid, which may be purchased ready prepared, or may be formed by heating potassium or sodium bichromate with sulphuric acid (1 part by weight of the bichromate, 3 parts of acid and 9 parts of water). In the type of cell shown in the figure the wire connected to the zinc rod is well amalgamated or coated with gutta-percha to insulate it. In the porous pot containing the zinc, there is put a quantity of mercury to maintain the amalgamation, and either dilute sulphuric acid or a solution of common salt NaCl. The chromic acid solution is placed in the jar containing the carbon plate.

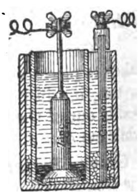

Fig. 3. Fuller's Mercury Bichromate Cell

The chemical reaction which takes place may be represented by the formula $3\,Zn + 2\,CrO_3 + 6\,H_2SO_4 = Cr_2(SO_4)_3 + 3\,ZnSO_4 + 6\,H_2O$.

This cell has an e.m.f. of about 2 volts, and is suitable for producing a fairly strong current for a short time. When much used the cell becomes saturated with the potassium and chromium sulphates, and a double salt, chrome alum, $K_2Cr_2(SO_4)_4$, crystallizes out and sticks so firmly to the bottom of the cell that it is somewhat difficult to remove.

Edison-Lalande Cell. — In this type of cell the positive pole is a plate of compressed cuprous oxide (CuO), the surface of which is reduced to metallic copper. The cuprous oxide acts as the depolarizer. The negative pole is amalgamated zinc and the electrolyte a strong solution (1 to 3 by weight) of caustic potash or of caustic soda.

A layer of heavy oil is poured over the solution to prevent evaporation and "creeping." No local action or polarization takes place in this cell; under normal conditions it is an easy matter to set it up to give any required number of ampere-hours, and to so proportion the constituents that they are all exhausted at the same time. This is a matter of considerable importance where closed-circuit working is employed, as in some systems of telegraphy and in alarm circuits. Although the e.m.f. of the Edison-Lalande cell is low, its resistance is also low, and the cell is capable of producing large currents. The cell may be left set up for months without deterioration.

The chemical reaction which takes place may be represented by the following formula

$$Zn + CuO + 2\,KOH = Cu + H_2O + K_2ZnO_2.$$

Leclanché Cells. — In the original form of this type of cell the positive pole was a plate of carbon embedded in a mixture of solid manganese peroxide and broken carbon contained in a porous pot. The electrolyte is sal ammoniac, NH_4Cl, and the negative pole zinc. The manganese peroxide acts as the depolarizer. The only object of the porous pot was to hold the carbon and manganese peroxide. In the later forms of this cell, such as the "agglomerate," Corsak, etc., the porous pot is dispensed with and a mixture of carbon and manganese peroxide are moulded together with a suitable binder, or the mixture of carbon and manganese peroxide is held together by a wrapping of canvas or sacking.

The chemical reaction which takes place may be represented by the formula

$$Zn + 2\,MnO_2 + 2\,NH_4Cl = Mn_2O_3 + H_2O + 2\,NH_3 + ZnCl_2.$$

If, however, too little sal ammoniac be present, zinc oxide or zinc oxychloride is formed instead of zinc chloride, and the solution becomes milky; hence when this happens, more sal ammoniac should be added.

The e.m.f. of a Leclanché cell is about 1.5 volts, but falls rapidly when the cell is used to send a strong current. It will, however, regain its value if the cell be left for some time unused, and it does not sensibly diminish when the cell is put to one side, even for some months. Hence, while the Leclanché cell is much inferior to the Daniell cell for the purpose of sending a steady current for an hour or two, it is much superior to the Daniell cell for producing intermittent currents at any time during the course of a year or more — for example, such currents as are employed for the ringing of electric bells, for house telephones, and for railway signaling.

Care of Leclanché Cells. — When the sal ammoniac becomes exhausted it should be thrown out and a new solution made. Three or 4 ounzes of sal ammoniac for a jar of ordinary size is required, the jar to be filled about one-third with water before putting in the electrodes.

DRY BATTERIES. — The modern dry battery may be looked upon as a modification of the Leclanché cell, the chief difference being that only enough water is added to the electrolyte to moisten an absorbent layer of pulp-board, blotting paper, cheese cloth or starch paste, this lining separating the positive and negative poles. The negative pole, which also serves as a container, is a hollow zinc cylinder, 6 inches high and 2.5 inches in diameter; the bottom of

this cylinder is also usually made of zinc. About 80 per cent of the dry batteries made in this country have these dimensions. The positive pole is a carbon rod, which may be either cylindrical or fluted. The absorbent layer above mentioned is placed next the zinc and is saturated with a solution of sal ammoniac and zinc chloride. The zinc chloride is necessary to reduce the rapid deterioration which would otherwise take place on open circuit. The space between this lining and the carbon electrode is filled with a mixture of granulated carbon and manganese peroxide, the latter being the depolarizer. The top of the cell is usually sealed with a pitch composition.

E.M.F. of Dry Batteries. — In new cells of practically all types the open-circuit e.m.f. is between 1.5 and 1.6 volts. The decrease in e.m.f. when the cell stands on open circuit is very slight, being only about 0.1 after the cell has stood many months. An open-circuit e.m.f. materially less than 1.5 volts is generally an indication of serious deterioration or of some other defect. The effect of temperature on the open-circuit e.m.f. is slight, amounting to only a few hundredths of a volt for all ordinary temperature ranges. Due to the relatively rapid polarization and increase of internal resistance with use, the average terminal voltage during the useful life of the cell is only about 1 volt.

Internal Resistance. — The internal resistance of a high-grade dry cell when new is usually less than 0.1 ohm, which may increase to 0.5 ohm within 9 or 12 months, even though the cell is not used during this time. The polarization of the cell in actual service causes a much greater decrease in the terminal e.m.f. than does the internal resistance drop, and therefore the internal resistance test is of little practical value.

Short-circuit Current. — Nine out of every ten users of dry cells consider the short-circuit current, i.e., the current produced through an ammeter having a relatively small resistance connected directly between the poles of the battery, as a direct measure of the value of the cell. There are other factors, however, which must be considered, such as the temperature of the cell, the service for which it is to be used, etc. According to D. L. Ordway (*Trans. Am. Electroch. Soc., 1910, Vol. 17, p. 346*) a standard 2.5 by 6-inch dry cell should give when new a short-circuit current (external resistance not over 0.01 ohm) of from 18 to 25 amperes; a cell giving a short-circuit current much above 25 or below 16 amperes should be looked upon with suspicion. A cell giving a short-circuit current much in excess of 25 amperes is liable to polarize rapidly, whereas if the short-circuit current is much under 16 amperes, it is probable that the cell has been made a long time or that cheap materials have been used.

The effect of temperature on the short-circuit current is pronounced. Between 10 and 80° C. the current increases about 1 ampere for each 10° increase in temperature. This effect is even more pronounced at very low temperatures. The short-circuit current returns to its normal value when the cell is restored to normal temperature.

Shelf-life. — The shelf-life of a dry cell of the ordinary sizes is usually considered as the time in months that the cell may stand on open circuit without its short-circuit current falling below 10 amperes. This current is about half the short-circuit current when the cell is new, and represents a value which is probably lower than the minimum point at which a dealer could dispose of a cell to the average consumer. The average shelf-life of high-grade cells is from 10 to 12 months, though the very best cells have a shelf-life of from 12 to 15 months. Many makes of cells have a shelf-life of only 8 to 10 months; and cells are on the market having a shelf-life of only 1 or 2 months.

The shelf-life is increased by storing the cells at a low temperature. Ordway gives the following results on standard dry cells kept in storage at the stated

temperatures. These cells give initially a short-circuit current of about 20 amperes.

Temperature at which cells were stored, ° C.	0	25	50	75
Short-circuit current at 25° C. after 5 months	18.1	17.4	0.5	0.4

Ampere-hour and Watt-hour Capacity. — The short-circuit current, however, is not a measure of the ampere-hours obtainable from the cell, as is indicated in the following table, taken from Ordway's paper. The ampere-hours given are those obtained from the various cells when discharged continuously through a resistance of 16 ohms until the closed-circuit voltage fell to 0.5 volt.

Brand of cell	A	D	G	J	M	P	V	X
Short-circuit current	33.0	24.5	22.5	20.9	20.1	19.2	11.6	6.6
Ampere-hours	24.0	33.5	40.0	18.2	11.7	30.3	13.6	4.5

The letters are arbitrary designations.

Although the short-circuit current falls off with the age of a cell, even though the cell is not used, the ampere-hour capacity does not decrease in the same ratio. Ordway gives the following tests on samples from the same lot.

	Freshly made	9 months after manufacture
Short-circuit current	22.4	3.6
Ampere-hour capacity (through 2 ohms to 0.25 volt)	24.9	20.2

Effect of Rate of Discharge on Capacity. — Ordway gives the following results of tests on standard 2.5 by 6-inch cells, when the cells are discharged continuously through 2, 4, 8, 16, 24, 32 and 40 ohms respectively. By "end point in volts" is meant the terminal voltage per cell at the end of the stated number of hours.

HOURS OF CONTINUOUS SERVICE OF 2.5 BY 6-INCH DRY CELLS

End point in volts	Resistances used in ohms						
	2	4	8	16	24	32	40
1.2	4.3	10	39	142	260	414	549
1.0	9.3	35	94	296	548	889	1148
0.8	16.5	51	143	414	751	1078	1550
0.6	28.2	76	225	954	1240	1600	1763
0.4	55	207	648	1197	1711	2280	2040
0.2	160	450	882	1318	1914	2626	3140

WATT-HOURS FROM 2.5 BY 6-INCH DRY CELLS DISCHARGED CONTINUOUSLY

End point in volts	Resistances used in ohms						
	2	4	8	16	24	32	40
1.2	3.7	4.3	8.1	15.2	18.8	21.7	23.8
1.0	6.7	13.0	16.5	26.9	33.4	39.8	42.0
0.8	9.7	16.3	21.5	32.8	40.3	44.6	50.6
0.6	12.5	19.4	26.6	48.9	49.5	52.7	53.2
0.4	15.4	27.3	39.1	52.6	54.3	58.2	54.8
0.2	19.8	32.6	41.5	53.3	55.2	59.3	57.1

Capacity on Intermittent Service. — Neither the ampere-hour nor watt-hour capacity of a battery on *continuous* service is a measure of its capacity on intermittent service. What the user wishes to know is the actual number of hours of service that he can obtain from a battery when used to operate a definite piece of apparatus, which as a rule takes current only intermittently, e.g., for telephone or ignition service. From curves given in Ordway's paper for 3 cells connected in series and discharged through the stated resistances the following table has been made up.

HOURS OF INTERMITTENT SERVICE OF 2.5 BY 6-INCH DRY CELLS

(The hours given are the hours the cell is actually supplying current)

End point in volts, 3 cells	Continuous discharge			5 minutes each hour night and day			5 minutes each hour, 8 hours per day, 6 days per week		
	5 ohms	10 ohms	20 ohms	5 ohms	10 ohms	20 ohms	5 ohms	10 ohms	20 ohms
3.6	4	12	30	4	45	80	3	15	45
3.0	9	25	65	29	65	145	12	30	60
2.4	15	40	100	48	90	190	23	45	75
1.8	25	60	150	65	130	225	35	70	100
1.2	42	140	475	80	160	250	52	100	150
0.6	95	...	...	93	200	290	70	115	165

From the above table it is apparent (1) that the terminal voltage falls off more rapidly on continuous discharge than on intermittent discharge, counting hours of *actual discharge* only, but (2) that during the latter stages the terminal voltage falls off more rapidly for the intermittent discharge, this latter effect occurring earlier as the external resistance is increased. The second effect is probably due to the deterioration of the battery while standing on open circuit. It should be kept in mind that the length of time the batteries were in service ... the intermittent tests were respectively 12 and 40 times the period of

Proper Arrangement of Cells for Best Results. — The data given in the above tables may be used as a basis for the determination of the number and proper arrangement of cells for a given service. For example, if a certain piece of apparatus has a resistance of 8 ohms and cannot be operated at a voltage under 0.8, then 143 hours of service can be obtained from a single battery. If however 4 cells in parallel are used, the drain on each cell will be one-fourth as great as before, which is equivalent to discharging each cell through 32 ohms. Therefore the 4 cells will give 1078 hours of service, or 270 hours per cell. If the 4 cells were connected in series, then drain on each would be 4 times as great as for a single cell, which is equivalent to discharging each cell through 2 ohms, but each cell could discharge to 0.2 volt instead of 0.8. The 4 cells in series would then give 160 hours, or only 40 hours per cell. The parallel arrangement is therefore the best in this case.

For ignition service 6 cells in series are usually required in order to obtain a sufficiently high voltage. On heavy service of this kind two or more such series groups connected in parallel are usually more economical than a single group. For telephone service 3 cells in series are usually required in order to obtain a sufficiently high voltage. For such light service a single group of cells is more advantageous than two or more groups in parallel; any gain which might at first sight be effected is more than offset by the deterioration caused by local action on standing. This may be seen by a consideration of the data on intermittent service given above.

Tests of Dry Batteries. — The proper testing of dry batteries has been the subject of considerable discussion during the last few years. See *Trans. Am. Electrochem. Soc.*, 1909 to date. A preliminary report was submitted by a committee of this society in April, 1912. The following is a brief summary.

In measuring the terminal voltage of a dry battery a voltmeter having a fairly high resistance, 300 ohms or more, should be used. The ammeter and leads for measuring the short-circuit current should have a combined resistance of 0.01 ohm. The internal resistance test is not recommended.

Service Tests. — Dry batteries to be used in telephone work should be tested by discharging 3 cells, connected in series, through 20 ohms rèsistance for a period of 2 minutes, each hour, during 24 hours per day and 7 days per week, until the closed-circuit voltage of the battery at the end of a period of contact falls to 2.8 volts (0.93 volt per cell). Report the results as the number of days during which the closed-circuit voltage remains above the limiting value of 2.8 volts.

For ignition service discharge 6 cells connected in series through 16 ohms resistance for 2 periods of 1 hour each per day, seven days per week. Determine at the end of every 12th period of closure the current which the 6 cells are capable of sending through a 0.5-ohm coil in series with an ammeter, the two being in parallel with the 16-ohm coil. The test is considered completed when the current through the 0.5-ohm coil at the end of a period of closure falls below 4 amperes. Report the results as the number of hours of actual discharge to this limiting value of the current.

For flash-light service discharge the battery through a resistance of 4 ohms for every cell in series, for a period of 5 minutes, once each day, until the closed circuit voltage at the end of a discharge period falls to 0.75 volt per cell in series. Report the result as the number of minutes of actual discharge until the voltage reaches this limiting value.

Full details for making these tests, together with a description of proper automatic arrangements for opening and closing the circuit at the designated times, will be found in the *Trans. Am. Electrochem. Soc.*, 1912, Vol. 21, p. 282. The timing device is an ordinary cheap clock provided with suitable contacts by means of which the hand closes the circuit.

Shelf-life Test. — Keep the cells open-circuited in a dry room at normal temperature. Determine the short-circuit current at the end of every 8 weeks. Report results as the number of months before the short-circuit current falls below 10 amperes.

COST OF DRY BATTERIES. — Dry batteries of standard size (2.5 by 6 inches) cost at retail from 10 to 25 cents, depending upon the quality of the battery. When bought by the barrel, good dry batteries may be had for 10 cents apiece.

Soc.*, particularly Ordway, D. L., *Some Characteristics of the Modern Dry Cell*, 1910, Vol. 17, p. 341, and *Report of Committee on Dry Cell Tests*, 1912, Vol. 21, p. 275 (which contains references to numerous other articles).

[H. PENDER AND H. R. RANKEN.]

BATTERIES, STORAGE, ALKALINE TYPE. — (*See also Automobiles, Electric; Batteries, Storage, Applications of; Batteries, Storage, Lead Type.*) The alkaline type of storage battery consists in its best-known form, i.e., the Edison battery, of an iron-nickel element immersed in dilute caustic-potash solution. The alkaline type of storage battery was first exploited commercially by Edison in 1904. At the present time (1914) it is being used extensively for the propulsion of electric vehicles, the operation of railroad block signals, the electric lighting of trains and the ignition and starting of gasoline engines.

THEORY OF ALKALINE STORAGE BATTERY.* — Numerous active elements have been used in the alkaline type of storage battery. The elements in the Edison type of alkaline battery consist of nickel hydroxide for the active material of the positive plate, iron for the active material of the negative plate and dilute potassium hydrate solution for the electrolyte. On discharge the iron is oxidized and the high nickel oxide is reduced to a lower oxide, while the electrolyte is not appreciably changed.

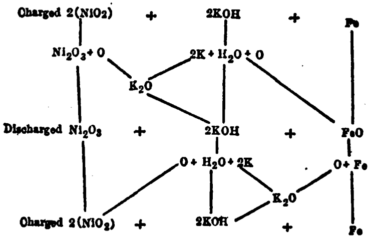
As far as the writer knows, an exhaustive study of all of the secondary reactions which take place during charge and discharge of this type of battery has not been made. It is generally conceded that the ultimate reaction of charge and discharge is simply a transference of oxygen backwards and forwards between the two electrodes. For this reason, only sufficient electrolyte need be provided to form a conductor between the positive and negative plates. A test of the electrolyte outside the pores of the plate shows that the specific gravity during charge and discharge does not vary to an appreciable extent.

The following simple reaction may be taken to indicate the probable final reaction on charge and discharge:

$$\begin{array}{cccccc} 2\,NiO_2 + 2\,KOH + & Fe & = & Ni_2O_3 + 2\,KOH + & FeO \\ +\text{ Plate} & -\text{ Plate} & & +\text{ Plate} & -\text{ Plate} \end{array}$$

This equation when read from left to right is the equation of discharge; when read from right to left it is the equation of charge. For simplicity, the water of the electrolyte has been eliminated from the equation. This, however, makes no difference, since it will be noted that the electrolyte indicated by 2 KOH remains unchanged whether the cell be charged or discharged.

Density of Electrolyte in Pores of Plates. — Although the density of the body of the electrolyte remains practically unchanged, it has been noted that, when the battery is on charge, the electrolyte becomes more dense in the pores of the iron plate and less dense in the pores of the nickel plate. A possible explanation of this action might be indicated by the accompanying diagram.



As neither potassium nor potassium oxide can exist in the presence of water, the reactions as shown in this diagram are necessarily hypothetical. However, although these elements cannot exist under these conditions, it is probable that the potassium oxide (K_2O) is formed in the pores of the cathode and immediately reacts with the water present in the electrolyte at this point, the result being a concentration of the solution at the cathode (iron plate) and a weakening of the solution at the anode (nickel plate).

* By T. Milton.

"Gassing." — In the alkaline type of cell, as in the lead type of cell, a certain amount of the water (H_2O) is broken up on charge by the electrolytic action of the charging current. The rate at which gas is evolved during a charge at the normal rate of current remains approximately constant during the first half of the charge, and increases rapidly during the latter portion of the charge. Of the total amount of gas evolved during a 7-hr. charge, about one-half is evolved during the first 5 hr. of the charge. As the oxygen and hydrogen thus liberated form an explosive mixture, provision should be made with a battery of any considerable size to carry the gases away to prevent their becoming a source of danger.

DESIGN.* — The only alkaline type of battery in use at present (1914) in the United States is that made by the Edison Storage Battery Co. This battery is made up of a positive plate having as the active material a high nickel oxide, a negative plate having as the active material powdered iron, and an electrolyte consisting of dilute potassium hydrate solution.

Positive Plate. — The positive or nickel plate consists of perforated steel tubes, nickel plated, filled with alternate layers of nickel hydroxide and pure metallic nickel in thin flakes. The nickel is added to give the necessary conductivity to the active material.

The tube is formed from a perforated ribbon of steel, nickel plated, and has a spiral lapped seam. This tube, after being filled with active material, is reinforced with steel bands, which prevent the tube expanding away from and breaking contact with its contents. The tubes are flanged at both ends and held in contact with a steel supporting frame or grid made of cold-rolled steel, nickel plated.

Negative Plate. — The negative or iron plate consists of a grid of cold-rolled steel, nickel plated, holding a number of rectangular pockets filled with powdered iron oxide. These pockets are made up of very finely perforated steel, nickel plated. After the pockets are filled they are inserted in the grid and subjected to pressure between dies which corrugate the surface of the pockets and force them into contact with the grid.

After the plates have been prepared, as outlined above, the positive or nickel plate is further oxidized electrolytically and the nickel hydroxide converted to a high oxide of nickel, probably NiO_2. The negative or iron plate is reduced electrolytically, the powdered iron oxide being converted into metallic iron. See section above on *Theory* for an explanation of the chemical action.

Separation and Insulation. — After the plates are assembled into a complete element, narrow strips of hard rubber are inserted between the plates to insulate them from each other. The side insulator is provided with grooves to insulate the complete element from the steel container. At the ends of the element, that is, between the outside negative plates and the container, are inserted smooth sheets of hard rubber. At the bottom, the element rests upon a hard-rubber rack or bridge, insulating the plates from the bottom of the container.

Assembly. — The jar is made from cold-rolled sheet steel, nickel plated. The walls of the jar are corrugated to give the greatest amount of strength with minimum weight.

The cover is of sheet steel, nickel plated, provided with three mountings, two being pockets for containing stuffing boxes about the terminal posts. The third mounting is an opening for filling the cell with electrolyte, and for the occasional (every four or five discharges) addition of distilled water to take the place of that which is lost during charge. This opening is provided with a

* By T. Milton.

hinged cap, on the under side of which is loosely hung a spherical segment of hard rubber. The latter, when the cap is closed, seats upon the circular opening beneath and is lifted by escaping gas, permitting its free egress. It closes the cell however to the admission of foreign gases or other material from without. The cap is opened only for filling and is held open or closed by a flat steel spring.

The plates are grouped on steel connector rods with steel spacing washers, all being attached to a steel terminal post. The terminal posts are insulated from the cover by means of hard and soft rubber washers and bushings.

The cells are assembled in wood trays, the positive and negative terminals of adjacent cells being connected together by copper connecting links. Each individual cell is insulated from the adjacent cell and from the containing wood tray.

RATING AND PERFORMANCE.—It is standard practice to rate an Edison battery in terms of the amperes it will give continuously for 5 hours. The rated capacity in ampere-hours is then 5 times this current rate. The normal rate of charge is the same as the normal rate of discharge and the time of normal charge is given as 7 hours. In the trade designations employed, e.g., A-6, the letter designates the size of the plate and the numeral the number of positive plates per cell, i.e., in the A-6 cell there are 6 positives; see below under *Dimensions, Weight and Cost*. The values of the rated current and output for each size of cell are given in the following table; the average voltage per cell during discharge is 1.2 volts.

RATED PERFORMANCE OF EDISON CELLS

Size of cell	Normal rate of charge and discharge, amperes	Rated capacity		Watt-hours per pound of cell for rated capacity	Average watts during discharge at normal rate
		Ampere-hours	Watt-hours		
B-2	8	40	48	10.4	9.6
B-4	16	80	96	13.0	19.2
B-6	22.5	112.5	135	13.7	27
A-4	30	150	180	13.3	36
A-5	37.5	187.5	225	13.4	45
A-6	45	225	270	14.1	54
A-8	60	300	360	13.1	72
A-10	75	375	450	13.2	90
A-12	90	450	540	13.2	108

The capacity of new cells increases for at least twenty cycles of charge and discharge. This betterment may be as much as 30 per cent above rating and comes from an improvement of conditions in the nickel electrode which is brought about by regular charging and discharging. It is expedited by over-charging. The capacity then decreases slowly with use until the electrolyte is renewed, which should be done before the capacity has fallen to the rated value. The capacity again increases for a few charges and subsequently falls.

Voltage Characteristics.—The charge and discharge voltage characteristics of an Edison battery vary with the conditions, among which are temperature, condition of electrolyte, time since last discharge or charge, etc. Typical

charge and discharge voltage curves at the normal rate are given in Fig. 1. It will be noted that the voltage rises rapidly at the beginning of charge, decreases somewhat during the second hour, and then rises gradually during the remainder of the charge. This hump in the voltage curve is characteristic of the Edison battery, and may lead to confusion as to battery's condition of charge. The value and duration of this hump may vary considerably even on successive charges of the same battery. The final charging voltage, with current on, is approximately 1.8 volts per cell, but ranges from 1.7 to 1.95 volts per cell. The rise in voltage near the end of charge is not sufficient to serve as a very satisfactory criterion of complete charge, but the Edison Storage Battery Co. recommends that if the extent of the previous discharge is unknown, the charge at the normal rate should be continued until the voltmeter reading has remained constant for 30 minutes at about 1.8 volts per cell.

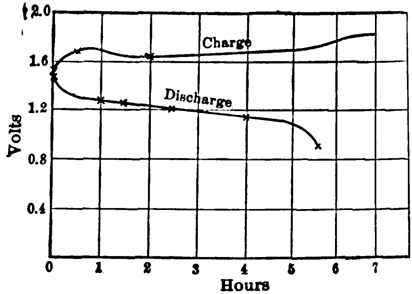


Fig. 1. Voltage Curves at Normal Rate

Effect of Temperature on Charging Voltage. — The normal average temperature of a battery on charge is between 90 and 100° F. The values of average and maximum charging voltage are higher for low temperatures of the electrolyte than for high temperatures. The range is indicated by the results of a series of tests given in the accompanying table.

Temperature, deg. Fahr.	Average voltage	Maximum voltage
35	1.88	1.94
55	1.81	1.92
75	1.76	1.88
95	1.70	1.84
115	1.67	1.77

Discharge Voltage. — On discharge the voltage performance of an Edison battery is more uniform than on charge, although during the early portion of the discharge the voltage is liable to vary considerably from the values indicated in Fig. 1. This depends chiefly on the length of time the cell has stood on open-circuit since the completion of the charge. The average discharge voltage is 1.2 volts per cell when discharged to 0.9 volt per cell (with current on) at the normal (5-hour) rate.

As with lead cells the open-circuit voltage is valueless as an indication of the state of charge. The open-circuit voltage in general will be about 20 per cent higher than the corresponding terminal voltage at normal rate of discharge.

Specific-gravity Characteristics. — The normal specific gravity of the electrolyte is about 1.200, and decreases slowly as the cell is used. (*See section below on Tests of Electrolyte.*) The specific gravity does not change materially on charge or discharge. A slight concentration has been noted on

discharge, but the variation is too small to have commercial significance. The specific gravity decreases 0.002 with each 10° F. increase in temperature.

Variation of Capacity With Rate of Discharge. — The ampere-hour capacity of an Edison battery is practically independent of the rate of discharge, provided the discharge is carried to a sufficiently low voltage. In this connection

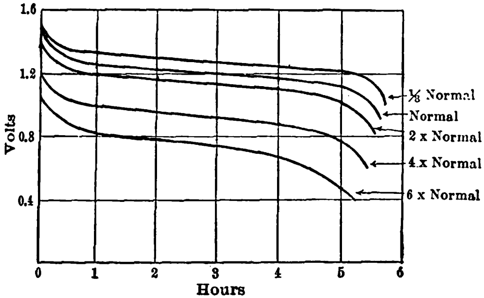

Fig. 2. Discharge at Various Rates

it may be pointed out that no harm is done an Edison battery by discharging it to a complete short-circuit. The total ampere-hour outputs of a battery when discharged to zero voltage at various current rates from one-third normal to four times normal, after a normal charge in each case, vary by only 2 per cent. As the low voltage part of a discharge cannot be considered useful, it is customary to consider the discharge completed for any rate of discharge when the voltage has reached a value differing from 0.9 volt per cell by an amount equal to the difference between the resistance drop in the cell corresponding to this rate and that corresponding to the resistance drop at the normal rate. Thus

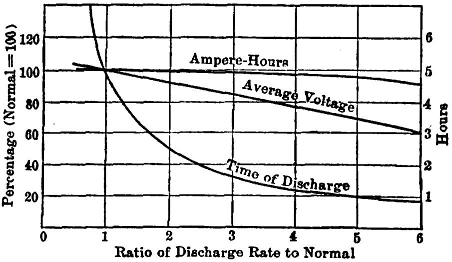

Fig. 3. Relation of Output Characteristics to Rate of Discharge

for a cell with an internal resistance (*for values see paragraph below on Internal Resistance*) of 0.003 ohm and a normal rate of 30 amperes, the terminating voltage for a discharge at 60 amperes would be $0.9 - 0.003\ (60 - 30) = 0.81$ volt. Fig. 2 shows a series of voltage curves for discharges at various rates following normal charges. The discharge has been discontinued in each case in accordance with the above rule. The variations of average voltage, ampere-hour output and time of discharge, with discharge rate are shown in Fig. 3, where values of these factors for the normal (5-hour) rate are each taken as 100 per cent.

Variation of Capacity with Rate of Charge. — The energy contained in a newly charged Edison cell depends upon both the rate and length of charge. Fig. 4 gives the variation in the time of discharge at normal rate for various charge rates and periods for a particular battery. In this particular test when the cell was discharged at the normal 5-hour rate to 0.9 volt, after a 7-hour

charge at this same rate it gave this current for 5.9 instead of 5 hours. The curve for the normal rate of charge shows that the capacity for a 10-hour charge is 13.5 per cent and for a 14-hour charge 22.0 per cent greater than for a normal (7-hour) charge. The results of a series of charges of various lengths and subsequent discharges, both at the normal rate, are given in the accompanying table.

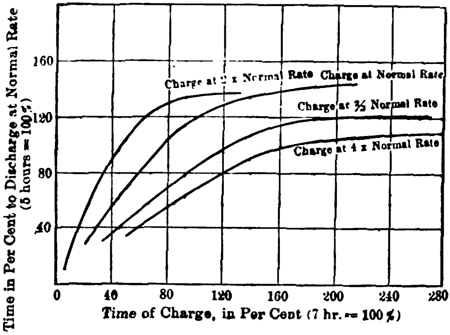

Fig. 4. Capacity at Normal Rate Discharge after Charging at Various Rates and Periods

Length of charge, hours	5.5	7.0	10.0
Length of discharge, hours	5.0	5.8	6.4
Average discharge voltage	1.19	1.202	1.203
Ampere-hour efficiency, per cent	91	83	64
Watt-hour efficiency, per cent	66	59	45

Variation of Efficiency with Length of Charge. — As shown by Fig. 4 the capacity of a cell depends upon the rate as well as upon the length of charge. For charge and discharge at the normal rate, the watt-hour efficiency is approximately 72 per cent for a short charge (i.e., one hour or less), it drops to about 58 per cent for a normal or 7-hour charge, and has smaller values for larger charges, being approximately 30 per cent for a 15-hour charge. The normal rate of charge has been chosen by the manufacturers such that for an output of approximately the rated number of ampere-hours at the normal rate the efficiency is higher for the normal rate of charge than for a rate which is considerably higher or lower than the normal.

Variation of Capacity with Temperature. — With the Edison battery, as with all alkaline batteries, there is a critical electrolyte temperature for each rate of discharge below which the capacity falls to a low value. The higher the rate of discharge the higher is this critical temperature. If the electrolyte throughout the cell has been chilled below the critical point for a given rate of discharge, the full capacity can be obtained as soon as the cell is warmed above the critical range. A series of tests, reported by W. E. Holland (*Central Station, Nov., 1911*), showed that the temperature should be kept above 55° F. if a large current is to be required. In the operation of Edison batteries in electric automobiles in cold weather it is recommended that the batteries be given a warming charge shortly before the car is taken from the garage. See also next paragraph.

Rate of Cooling of Electrolyte. — The rate of cooling of the electrolyte

contact with the battery, the temperature of this air, and the rate at which current flows from the battery. Another series of tests reported by Holland (*Central Station, Nov., 1911*) showed that in an open box a battery which had been charged in a room temperature of approximately 65° F. could stand idle in still air at 8° F. for a period of about 4 hours before the electrolyte dropped to 55° F. When placed in a closed box it took about 13 hours for the battery to cool from an initial temperature of 90° F. (which a battery would have at the end of a normal charge) to the critical temperature for high discharge rates. These tests pointed out the efficacy of a closed battery box for keeping cells warm. (*See also Automobiles, Electric.*)

Internal Resistance.—The effective internal resistance of a cell determines the immediate change in voltage at the cell terminals with a sudden change in the discharge rate. For method of measuring see section on *Testing*, below. The value in ohms of the mean effective internal resistance for an A-type cell discharging at normal rate is approximately equal to 0.012 ohm divided by the number of positive plates as given by the designation of the cell size, and for a B-type cell is approximately equal to 0.024 ohm divided by the number of positive plates. For two or more cells in series the total effective internal resistance is the product of this value by the number of cells in series. The internal resistance of Edison cells is such as to cause an immediate drop in terminal voltage of between 7 and 8 per cent with a sudden increase in current equal to the normal rate. The virtual internal resistance increases slightly during the progress of a discharge.

Retention of Charge.—The rate of loss of charge of a battery during idleness varies with the temperature at which it stands. The loss is slight in the cold and becomes greater as the temperature increases. The variation for cells charged under normal conditions and discharged after resting for various periods in one case at normal temperature of 75° F., and in another case at 35° F. is shown in Fig. 5. Accordingly a cell which has not been used for 10 days following a normal charge may be expected to retain at least 85 per cent of its initial capacity. It will be noted that the *rate* of loss of capacity after the second day is practically the same at both temperatures.

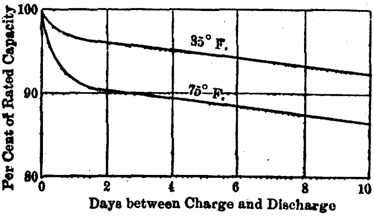

Fig. 5. Retention of Charge when Standing Idle

TESTING.—There are described below only those tests which are of interest in the commercial operation of the batteries. The methods of conducting several of the tests are the same as for the lead type of battery and are described more fully in the article on *Batteries, Storage, Lead Type*.

Tests of Electrolyte.—The normal specific gravity of the electrolyte at 80° F. is 1.200 as measured by hydrometer but may range from 1.160 to 1.230. Specific gravity is not necessarily a true indication of the suitability of the electrolyte, since harmful impurities may get into the electrolyte when watering or in other ways. The manufacturers recommend that the electrolyte be removed when the specific gravity has fallen to 1.160; this will usually be required after from 8 to 10 months of daily service. It is advisable to discharge the battery before renewing the electrolyte, and to give it a 12-hour charge, at the normal rate after renewing.

Test for Internal Resistance. — The internal resistance of a battery may be determined by momentarily opening the switch during discharge and noting the rise in voltage. This rise represents the *IR* drop in the battery due to its internal resistance and cell connections. Hence the value of the internal resistance at the given point of discharge will be the quotient of the volts rise divided by the current rate. This value divided by the number of cells in series will give the internal resistance per cell. Since on interrupting the current the voltage may rise for some time, due to change in the e.m.f., a better voltage reading may be obtained by momentarily reducing the current flow instead of opening the circuit. In this case the resistance is found by dividing the difference in voltage at the two rates by the change in current.

Capacity; Efficiency. — In testing for the capacity of an Edison battery at any given rate, the discharged battery should first be charged for 7 hours at the normal (5-hour) discharge rate. The battery is then discharged at the desired constant-current rate until the terminal voltage has reached the value as determined by the rule given in the paragraph above on *Variation of Capacity with Rate of Discharge*. The capacity in ampere-hours is the product of time of discharge in hours by the rate of discharge in amperes. The watt-hour efficiency of the battery is the ratio of the energy given out on the discharge to the energy put in on the charge. The term "volt efficiency" is used to express the relation of the average voltage of discharge to the average voltage of charge. For charge and discharge at the normal rate the value of the volt efficiency will be close to 72 per cent for any length of charge not extremely short or long. Thus 72 per cent is the limit of possible efficiency at the normal rate. The watt-hour efficiency on any normal rate test may be calculated accurately enough for all practical purposes by taking 72 per cent of the ampere-hour efficiency, i.e., by taking 72 per cent of the ratio of ampere-hours output to ampere-hours input.

Test Electrodes. — The best substance for a third electrode in analyzing voltage curves of alkaline batteries is a partially reduced oxide which will undergo reduction in the electrolyte without polarization, and which is insoluble in the electrolyte. Either cupric oxide or the high nickel oxide of a charged Edison positive fills these conditions for alkaline cells. For a discharge at normal rate the readings of the cell electrodes to a test electrode of cupric oxide are: iron, approximately 0.44 volt, nickel, 0.9 to 0.5 volt; for a test electrode of nickel oxide the readings are: iron, approximately 1.28 volts, nickel − 0.1 to − 0.4 volt.

INSTALLATION. — The A- and B-types of cells are usually assembled by the manufacturer in wooden trays holding from 2 to 12 cells each, according to requirements. There is an air space between cells for ventilation and insulation. The standard form of tray is made "bottomless," in order to prevent short-circuits between cells from the collection of dirt and moisture. If A-type cells are to be used where they will be pulled horizontally for filling, etc., trays with bottoms are used on account of the greater strength. Data on typical assemblies in bottomless trays are given in the following table:

Size of cell	B-2	A-4	A-8	A-12
Width of standard tray, in.	6⅛	6⅛	6⅛	9
Over-all height (filler cap closed), in.	9⅝	14 5/16	14⅞	15½
Length of trays, in.:				
2-cell tray	5	7¾	12⅞	13¾
5-cell tray	10¾	17⅛	29¾	32½
8-cell tray	16⅝	27¼	47⅜	....
12-cell tray	24⅜	40½	....	....

For the extra high container which is sometimes furnished (designated by *H*) the over-all height for B-type is 2 in. greater and for A-type 3 in. greater than the figures given in the above table.

The over-all height with filler cap open is about 1½ in. greater than the height with filler cap closed.

If a battery is to be used for stationary service a clearance of 6 in. above cells should be allowed so as to permit the proper filling of the cells in place. In vehicles from which the battery is removed for filling the clearance need be only ¾ in.

OPERATION.—An Edison battery should never be operated in any manner except in accordance with the instructions received from the Edison Storage Battery Co. Disobeying these instructions may result in forfeiture of the guarantee with regard to the life of the cell. As the detailed instructions differ somewhat for various services, only general directions which apply to all services are noted below.

Charging.—The batteries are usually shipped in a discharged condition. The initial charge should continue for 12 hours at the normal rate. A similar overcharge should be given after 30 days of service, one after 60 days of service, and another after each renewal of electrolyte. The normal charging rates are given above in the section on *Rating and Performance;* the time of a normal charge is 7 hours. The boosting rate may be as high as desired provided the temperature does not exceed 115° F. in any of the cells. The best results are obtained when the temperature is kept between 75 and 95° F. Under average operating conditions the charge in ampere-hours necessary to replace a discharge is from 15 to 25 per cent greater than the discharge. The Edison Storage Battery Co. recommends that if an ampere-hour meter is used, it should be set to operate 20 per cent slow on charge.

Precautions as to Gases.—The battery should be well ventilated while charging, and no open flame or arcing contact should be allowed near the cells while charging or immediately afterward, as the evolved gases may be exploded.

Standing Idle.—An Edison battery may be allowed to stand idle in any state of discharge provided the level of the electrolyte is kept above the plates. After long idleness an overcharge may be required to bring the battery up to rated capacity.

Watering Cells.—The level of the electrolyte must be kept above the plates by adding distilled water from time to time. The frequency of adding water will depend upon the amount and rate of charging. The manufacturers of the battery supply an indicating filler which is of assistance in preventing slopping and over-filling.

Cleaning.—The trays and containers must be kept dry, and dirt or other foreign material must not be allowed to collect between or under cells. Dirt and dampness may cause leakage which may result in corrosion of the containers. The outside of the cans may be cleaned with a steam or air blast. If a container becomes leaky it should be returned to the manufacturer for repair.

DIMENSIONS, WEIGHT AND COST.—The Edison battery is made in two standard types, the plates of the A-type being approximately 4¾ by 9¼ in. and those of the B-type 4¾ by 4⅝ in. Plates of other dimensions can be obtained for special purposes. The sizes of cells are commonly designated by the type letter and a number which indicates the number of positive plates, as for instance, an A-6 cell has 6 positive and 7 negative plates. The several sizes of cells together with data on the dimensions and weight of each are given in the following table:

DIMENSIONS AND WEIGHTS OF EDISON CELLS

Size of cell	Over-all dimensions of cell, in inches			Weight in pounds	
	Length	Width	Height	Complete cell	Average per cell with trays and connectors
B-2	1.5	5.1	8.8	4.6	5.5
B-4	2.6	5.1	8.8	7.4	8.7
B-6	3.8	5.1	8.8	11.0	12.0
A-4	2.7	5.1	13.4	13.3	14.5
A-5	3.2	5.1	13.4	16.8	18.5
A-6	3.8	5.1	13.4	19.0	21.0
A-8	5.0	5.3	14.0	27.0	30.0
A-10	6.2	5.5	14.0	34.0	37.5
A-12	7.4	5.5	14.6	41.0	45.0

For services, such as the lighting of railroad cars, which require that the batteries work for long periods without the addition of water, the A-type plates are assembled in containers (designated by H) about 3 in. higher in each case than those indicated in the table, in order to obtain additional space above the plates for the electrolyte. The weight per cell is then about 15 per cent greater than the above.

The cost of Edison cells assembled in trays is approximately $1.00 per pound, including weight of trays and connectors. This is equivalent to a cost of approximately $420 per kilowatt at the normal (5-hour) rate of discharge or $125 per kilowatt at the one-hour rate of discharge. The manufacturers guarantee that these cells will show at least their rated capacity after being used a specified time, the usual guarantee period for A-type cells being 4 years and for B-type cells, 5 years.

BATTERIES, STORAGE, APPLICATIONS OF. — (*See also Batteries, Storage, Alkaline Type; Batteries, Storage, Lead Type.*) The following list shows some of the more important applications of storage batteries.

Central Stations:
- Emergency reserve — "Stand-by service," p. 88.
- Load or voltage regulation, p. 90.
- Taking peaks, p. 95.
- Day load on small systems, p. 96.
- Exciter reserve, p. 92.
- Remote-control switch operation, p. 93.

Isolated Plants:
- Mine hoists, steel mills and other heavy motor regulation (*see Index*).
- Carrying entire load during certain hours of light load.
- Load and voltage regulation in office buildings or hotels, where electric elevators are in service, p. 98.
- Giving 24-hour service in residences.
- Operation of drawbridges, p. 101.

Other uses are:
- Regulation of long feeders, see *Trolley Systems, Overhead*.
- Propulsion of pleasure cars, trucks, street cars, submarine boats, launches, etc., p. 100.
- Gas-engine ignition, p. 102.
- Railway passenger-car lighting, see *Lighting of Trains by Electricity*.
- Railway signaling, see *Signaling, Railway*.
- Telephone and telegraph (q.v.)
- Portable and small stationary lamps.
- Fire and burglar alarm (q.v.)
- Electroplating, p. 102.
- Dental and other surgical work.

Probably the largest application of storage batteries at the present time is for "stand-by" service in central stations, for peak and regulating work in railway power stations, in electric vehicles and in the steel-mill power stations where the load fluctuations are very rapid and of great magnitude.

Extent of Application in the United States. — The first application in America of storage batteries to central-station service was in 1886. In 1912, there were in service in the United States, for central-station "stand-by" work, 185 storage batteries of the lead-lead acid type, having a combined capacity of approximately 147,000 kw.-hr. at the one-hour rate of discharge. Twenty-one of these are of the Faure or Pasted type, the rest being of the Planté type, or a combination of Planté and Faure types.

In railway power stations there were in service in the United States in 1912 batteries of the lead-lead acid type aggregating approximately 120,000 kw-hr. at the one-hour rate of discharge. All of these batteries are of the Planté or combined Planté and Faure type.

There were in service in steel-mill power plants in the United States in 1912 twelve batteries of the lead-lead acid type aggregating approximately 7000 kw-hr. at the one hour rate. All of these batteries are of the Planté or Planté Faure type.

There were in service in the United States in 1912 approximately 500,000 cells of the lead-lead acid type, operating telephones, lighting railway cars and operating signals. There are probably over 400,000 lead storage-battery cells in operation in electric automobiles.

STAND-BY BATTERIES IN CENTRAL LIGHTING STATIONS.— Formerly the storage battery in a central lighting station served a dual purpose: first, as a source of current in an emergency, and second, to take short peaks of load, thus cutting down the generating capacity in service and increasing the economy of plant operation. In certain cases the batteries are used in this manner to-day, but owing to the desire always to have the full battery reserve in case of emergency, the peak battery feature is being abandoned and the stand-by feature only is being retained.

This method is considered by some authorities to be even more conducive to economy of station operation than that in which the battery was also used on the peak, inasmuch as the presence of a fully charged battery behind the generating apparatus permits station operation at a much higher load factor than were the battery fully or partly discharged. Furthermore, as one of the important factors in the life of the battery is the amount of work it does, this life is greatly increased if the battery be used only for emergency service.

Connections for Battery and Its Auxiliaries, Stand-by Service.— Fig. 1 shows a general standard scheme for the operation of a battery on a 3-wire lighting system, either for peak work or stand-by emergency work. As will be noted in this scheme, the neutral of the battery is connected to the neutral of the system.

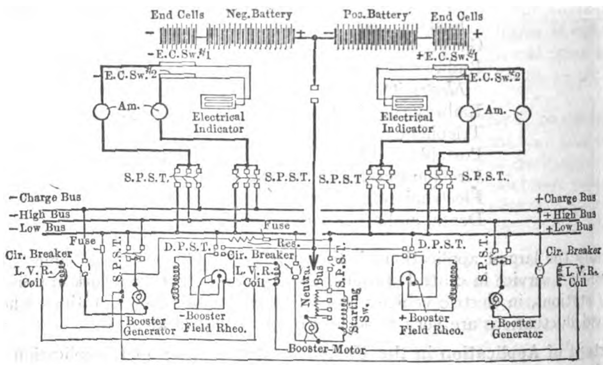

Fig. 1. Connections for Stand-by Service

Charging. — For stand-by emergency work it is standard practice to take the battery off the bus for charge and in most cases the battery is floated on only one bus. In this service the battery is kept fully charged and floating on the bus-bars continuously, except during charge. Except in case of an emergency discharge having been required from the battery, it will only be necessary to give the battery an occasional overcharge about once a week or once in two weeks in order to keep the active material in proper condition. Since this overcharge is given at the normal rate for only a few hours, once every week or every two weeks, a time for this overcharge can be selected when it will be safe to take the battery off the bus. It will also be noted that on charge, sufficient voltage is obtained for charging the complete battery by adding to the bus voltage the voltage of a simple charging booster. It is necessary with the 3-wire system to have two generators, one on each side of the system, in order to be able to charge the two halves of the battery at different rates in case the battery has become unbalanced on discharge. The diagram shows a simple shunt motor driving these two booster generators.

End-Cells and Switches for Stand-by Service. — The connections between the two sides of the battery and the outside bus-bars of the system are made through "end-cell switches," by means of which the number of cells on the system can be varied at will within certain limits. This scheme shows two end-cell switches in parallel on each side of the system, this number of switches being installed in this case in order to provide sufficient capacity for the discharge.

The number of end-cell switches necessary on each side of the system depends upon the current to be carried, upon the number of bus-bar voltages to be maintained from the battery simultaneously, and upon whether or not it is desired to keep the battery on the bus during charge. It is frequently required to float the battery on more than one bus. In such cases there must be one end-cell switch on each side of the system for each bus. If it is not desired to keep the battery on the bus during charge, and if the battery is to float on only one bus, one end-cell switch on each side of the system will be sufficient, provided the one end-cell switch has sufficient current-carrying capacity.

If, however, it is deemed advisable to keep the battery on the bus at all times, it will usually be necessary to have at least two end-cell switches on each side of the system and the number of end cells required will be greater than the number of end cells required where the battery can be taken off the bus for charge. This point is referred to again in the next section.

It will be noted from the diagram in Fig. 1 that on discharge the cells are connected in series and that the voltage on discharge is controlled by means of the end cells.

Importance of Well-designed End-cell Switches. — It should be noted that the end-cell switches used with this standard scheme are by far the most important of the auxiliary apparatus and the efficacy of the battery is absolutely dependent on the successful operation of these end-cell switches. The factors necessary for successful operation of the end-cell switches are, first, there must be no chance of interruption of the battery discharge; second, the switch must be able to carry the required current without dangerous heating or sparking. End-cell switches having a continuous current-carrying capacity of 10,000 amperes are now on the market. These switches can carry 40,000 amperes for six minutes and the contact brushes can be moved from point to point without injurious sparking or heating.

Number and Capacity of Cells for Stand-by Service. — The number and the capacity of the cells depends upon the lowest bus voltage maintained under normal operating conditions, the minimum allowable voltage at the end of discharge in case of emergency, and the load required to be carried during emergency.

If the battery can be taken off the bus for charge, the number of cells in the main battery will be equal to the lowest bus voltage (between outside bus bars) divided by 2.1. The number of cells in the entire battery will be equal to the lowest allowable voltage in emergency divided by the final voltage per cell at the rate of discharge required by the emergency. The difference between the number of cells in the main battery and the total number of cells will, of course, be the number of end cells. When the total number of cells in the battery is determined it will become necessary to put half the number of cells, including half the end cells, on each side of the system.

If it is deemed necessary to keep the battery on the bus at all times during charge and discharge, the total number of cells will be determined as indicated above, but the number of cells in the main battery will be equal to the bus voltage divided by 2.7, since this is the average cell voltage at the end of charge. In this case, at least two end-cell switches on each side of the system will be

required. On charge one end-cell switch on each side of the system is connected to the main bus and is set at such a position that the total voltage of the cells in circuit during charge equals the bus voltage. The other end-cell switch is set so as to include the cells being charged. That is, at the start of charge, the circuit from the charging booster to one end-cell switch will include all of the cells, and the circuit from the lighting bus to the other end-cell switch will only include sufficient cells to give the lighting-bus voltage. As the charge proceeds, the end-cell switch in the charging circuit will be shifted to cut out end cells as their charge is completed, and the end-cell switch connecting the battery with the lighting bus will be shifted to cut out cells as the voltage of the battery comes up, so that the voltage of the cells in circuit on the lighting bus can be held at the lighting-bus voltage.

It is seen that with this operation the end-cells included between the two end-cell switches will have to carry the charging current plus or minus any current transferred between the battery and the lighting bus. It is thus apparent that with this method of operation, unless especial care is taken to float the battery at the true lighting-bus voltage, the end cells will be worked unequally. It is also seen that, if it is desired to keep the battery on the bus at all times, the amount of end-cell copper is considerably increased and the cost of the battery installation is proportionately increased, for the number of end-cells required is greater than the number of end cells required when the battery can be taken off the bus for charge. On account of this increase in cost and the possibilities of unequal work on the end cells, it is desirable to install the simpler scheme shown in Fig. 1.

Determination of Size of Stand-by Battery.—As an example of the method used in determining the number and capacity of cells required for this class of work, suppose it were desired to install a battery to take care of an emergency of 20,000 amperes for 20 minutes at a normal bus voltage of 230 volts with a minimum allowable voltage during emergency of 225 volts. The 20-minute rate of discharge is 8 times the normal rate, as shown in Figs. 3 and 6 in the article on *Batteries, Storage, Lead Type*, and it will be noted from Fig. 6 that the final voltage per cell at the end of this rate is 1.5 volts. The total number of cells will be 225 divided by 1.5, or 150 cells. If it is desired to use standard practice, taking the battery off the bus for charge, the number of cells in the main battery will be equal to the normal bus voltage, 230, divided by 2.1, or 110 cells.

It will, therefore, be necessary, in this case, to install a battery having 150 cells, including 40 end cells, each cell having a capacity of 20,000 amperes for 20 minutes. This battery will be installed with 75 cells, including 20 end cells, on each side of the neutral. In standard stand-by practice the 20 end cells on each side of the neutral will be connected to the end-cell switches, with one cell per switchpoint for a few of the cells and with 2 or 3 cells per switchpoint for the remainder of the end cells. A certain number of single-cell connections will be required in order to take care of the variation in the bus voltage, as it may be necessary to cut in and out cells while the battery is floating. The rest of the equipment necessary should be in accordance with the diagram shown in Fig. 1.

LARGE REGULATING BATTERIES FOR RAILWAY WORK, ETC.—Often the load (particularly a railway load) on the power house is subject to frequent and violent fluctuations, causing severe strains on the generating apparatus in service and in many cases requiring the operation of a greater number of units than would be necessary to furnish a steady average load. This not only results in a lower load factor and consequent loss of economy, but it reduces the surplus capacity of the generating station by the extra

amount of apparatus required in operation. Another loss in economy is due to the rapid changes in the cut-off point of reciprocating engines, due to the violent fluctuations of load. Fig. 2 shows a simplified wiring diagram of the scheme generally used.

Carbon Regulator. — The carbon regulator shown in Fig. 2 consists of piles of carbon disks arranged in two groups on opposite sides of the fulcrum of a lever, the lever being subjected at one end to the tension of a spring and at the other end to the pull of a coil connected in series with the main bus-bar. Variations in the force applied to opposite ends of this lever will increase the pressure on one group of carbon disks and decrease the pressure on the other, thus varying their relative resistances. These piles are connected in series across the battery terminals, and the field winding of the booster exciter is connected between the middle point of the battery and a point in the circuit between the two groups of carbon disks. Variation in the resistances of these two piles, produced by variation of the pressure of the lever, will cause current to flow in one direction or the other through the field of the exciter, thus controlling the operation of the booster and compelling the battery to charge and discharge with small variations of current in the series coil.

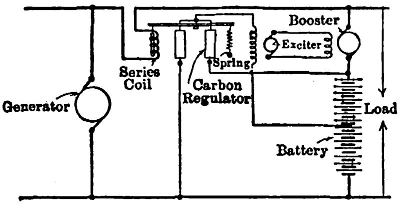

Fig. 2. Connections for Regulating Service

In this manner the load on the generator can be maintained constant within a few per cent on either side of the average value for which the apparatus has been adjusted. The load on the generator is determined by the tension of the spring, which may be adjusted to balance any average current in the series coil. If the average load on the line should exceed for a considerable period of time the generator load for which the spring is adjusted, the battery will be subjected to a sustained discharge which may in time exhaust its available capacity. If, on the other hand, the average load on the line falls off for a considerable period of time, the battery will be subjected to a sustained charge which may produce excessive and unnecessary overcharge. To follow these variations in average load, it is necessary to adjust the spring from time to time.

Automatic "Average" Adjustor. — In order to eliminate the necessity for such frequent adjustment by hand in cases where the average load is continually changing and where the generator is capable of handling these comparatively slow changes, the automatic average adjustor has been designed. This piece of apparatus consists of a small motor connected by a reducing gear to the drum which controls the tension of the carbon regulator spring. The armature of this motor is connected across the main bus-bars through a fixed resistance which maintains a practically constant current through the armature. The field of the motor is connected across the terminals of the booster.

Whenever the booster voltage is in the direction to discharge the battery, the motor field is energized and the motor revolves in the direction to increase the tension of the spring, thus gradually increasing the load on the generator and relieving the battery of its discharge until the booster voltage comes back to zero. If, on the other hand, the booster voltage is in the direction to charge the battery, the motor of the average adjustor will operate in the opposite direction, gradually relieving the tension on the spring and reducing the average load on the generator until the booster voltage is again brought back to zero

and the battery is again restored to its floating condition. This transfer of load between the battery and generator is brought about slowly so that the battery is still free to relieve the generator of all quick fluctuations of load. The battery, however, is relieved from a considerable amount of sustained peak charge and discharge.

Load-limiting Device. — To prevent the average adjustor from throwing load on the generator beyond its capacity, a load-limiting device has been designed. This consists of an electrolytic valve in series with the field of the motor. Ordinarily this valve is short circuited by a switch. When the drum which regulates the tension of the spring has traveled to a certain point corresponding to the maximum permissible load on the generator, a projection mounted on the shaft of this drum engages with the switch and opens it, whereupon the valve prevents current from passing through the motor field in a direction to cause a further increase in the spring tension. The valve will, however, permit the current to flow in the opposite direction so that as soon as the load has decreased sufficiently to cause the battery to charge, the motor will operate so as to relieve the tension on the spring and at the same time permit the switch to close, thus restoring the original adjustment.

Automatic Current Stop. — While the capacity of a storage battery to withstand an excessive momentary overload without injury is practically unlimited, the booster must be protected by an automatic circuit breaker. Whenever the setting of this circuit breaker is exceeded on heavy overload and the breaker opens, the entire maximum load is thrown on the generator. This usually results in opening the generator circuit breaker also and interrupting the supply of current to the line. To avoid this and permit the battery to furnish the maximum current which the booster can handle without danger of overloading the latter or opening the circuit, there has been designed an automatic current stop. This stop is arranged to automatically prevent the battery from discharging above a certain predetermined value, for which this stop has been adjusted. All load demand above this predetermined value is thrown upon the generator. The generator is thus subjected only to the excess of load above the maximum capacity of the battery booster, instead of having the entire load of the line suddenly thrown on it when the battery circuit breaker opens. The adjustment of this automatic current stop can be changed within certain limits to meet the requirements.

Batteries for Controlling Alternating-current Loads. — For controlling fluctuations of an alternating-current load a solenoid which is responsive to the energy component of the alternating current is substituted for the series coil shown in Fig. 2. The general operation of this scheme is the same as described above, except that it is, of course, necessary to discharge the battery on to the alternating-current bus through suitable alternating-current-direct-current transforming apparatus. There are in service at present several battery installations which regulate fluctuating alternating-current loads. Most of these installations are based on the carbon regulator principle, as outlined above.

Number of Cells and Capacity of Cells and Booster. — The number and capacity of cells required for regulating work depends upon the bus voltage and upon the nature of the fluctuating load. It is also frequently desirable to utilize a regulating battery for emergency and peak work, and the extent of the emergency and peak requirements will also be a factor in fixing the capacity of the battery. The number of cells installed will be equal to the bus voltage divided by 2.1, since this is the floating voltage per cell. A reference to Fig. 2 shows that during the regulation of load fluctuations all of the battery discharge passes through the armature of the booster generator. It is thus seen that it ... for the booster to generate sufficient voltage to make up for the drop

in battery voltage on discharge. This drop in battery voltage depends upon the capacity of the battery, and the amount and duration of the discharge. Before the booster can be properly designed it will be necessary to have complete data on these points.

Emergency Work. — For emergency work, where the battery is carrying the entire load without the assistance of any generating apparatus, it may or may not be necessary to keep the booster in circuit, depending upon whether or not it is desired to maintain a constant bus voltage. If it is not desired to maintain a constant bus voltage, a saving can be effected by cutting the booster out of circuit and allowing the battery to discharge directly on to the system.

Peak Work.— For peak work, where the battery must work in parallel with the generators, it will either be necessary to keep the booster in circuit in order to maintain the same voltage as the generator or else to give the generators a drooping characteristic so that the battery can discharge in parallel with the generators without the aid of the booster.

Current Capacity. — If it is desired to float the battery on the system at all times in order to regulate load fluctuations, it will be possible to float the battery about 75 per cent fully charged. If this battery must have a definite capacity always available for peak or emergency work, it is seen that the battery must be of sufficient capacity, when 75 per cent fully charged, to deliver the load called for by the emergency or peak conditions.

Determination of Size of Regulating Battery. — In all cases where a battery is to be considered for any one of the above conditions or any combination of them, it is recommended that the complete data summarized below be sent to the battery manufacturer with a request for a complete report covering the battery and accessories recommended to suit the conditions. The data necessary are as follows:

Number, type and capacity of boilers, if the plant is a steam plant.
Schedule of boiler operation, if the plant is a steam plant.
Number, type and rating of generators.
Schedule of generator operation.
Bus voltage maintained.
If the generators are of the alternating-current type, give frequency, number of phases, and the number and rating of any static transformers used.
If the station in question is a substation, describe the complete substation equipment along these same lines.
Give complete 24-hour load curve showing half-hour readings of the total load on the station bus bars. A graphic recording meter chart will be sufficient, if such an instrument is available.
If possible, obtain five-second readings on the total indicating ammeter or wattmeter, over a period of one-half hour during the time of maximum fluctuations.
If the battery is required to assist the generators on the peak, give the amount of load in kilowatts required from the battery and the length of time this load is required. It would be well to have an exact load curve showing the shape of this peak, if it is possible to obtain such a record.
If the battery is to be used for emergency, give the amount of the load and the time over which this emergency extends. In all cases state the exact nature of the load required, that is, whether it is a motor load, a lighting load, etc.

BATTERIES FOR REMOTE-CONTROL SWITCH OPERATION. — It is standard practice in central stations of any magnitude to install a storage battery of sufficient capacity to give ample insurance against interruption of

the switch-control circuit. It is the usual practice to utilize this battery, not only for the operation of the remote-control switches, but for the operation of the signal lamps and a sufficient number of emergency lamps throughout the station. In some stations the remote-control switches are operated from the exciter bus bars, but it is better practice to operate these switches together with their signal lamps and the emergency lamps from a separate source of power.

Control Battery Connections. — Fig. 3 shows a scheme which is more or less standard with the larger central-station companies. This figure shows a motor-generator set consisting of an induction motor driving a direct-current generator whose voltage can be varied from 110 volts up to 168 volts, the latter voltage being required to completely charge the 62 cells in series.

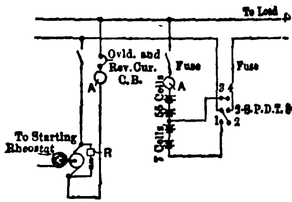

Fig. 3. Connections for Control Battery

Under normal operation the battery is floated on the 130-volt bus with the motor-generator set, the battery switches being thrown into positions 1 and 2. It will be noted that with this arrangement all 62 of the cells are floating on the bus. When it becomes necessary to charge the battery, the battery switches are thrown into positions 1 and 4, and the generator voltage is raised sufficiently to start the charge of the entire 62 cells. With this arrangement the voltage at the load bus bars will be the voltage of 55 cells. At the finish of charge the battery switches are thrown into positions 3 and 4. It will be noted that in these positions the group of 7 end cells is out of circuit, as they have received their complete charge, and the motor-generator set will be furnishing power to charge the 55 cells and to carry the load.

Size of Battery. — With this arrangement the voltage at the bus bars may vary from 145 volts to the *minimum* voltage of the battery on discharge. The number of cells for this scheme can be varied to suit the voltage conditions. The capacity of the battery is fixed by the maximum current demand, the total ampere-hour current demand over the period of estimated possible shutdown, and the minimum allowable voltage on the load bus bars. With these conditions known, it will be possible with the aid of trade catalogues showing the charge and discharge curves of the battery and the battery capacity at various rates, to select a battery to suit the conditions.

Control Battery on Exciter Bus. — If the oil-switch load is furnished from the exciter bus it will be necessary to float the emergency battery on the exciter bus, or to supply automatic means for throwing the battery on the exciter bus when the voltage of the exciter bus drops below a certain predetermined value. If this method is used, unless the battery is of sufficient capacity to carry the entire exciter load, it will be necessary to place a reverse-current circuit breaker between the battery and the exciter load, so that when the exciter bus "goes dead" the battery will be automatically cut off from the exciter bus and left on the remote-control switch bus.

EXCITER BATTERIES. — It is standard practice with the larger central-station companies to install a battery of sufficient capacity to carry the total maximum exciter load for from one hour to two hours continuously. The number of cells will depend upon the voltage of the exciter bus, which is usually 110 but is sometimes as high as 250 volts.

If it is desired to maintain constant the voltage on discharge, it will be necessary to utilize end cells by means of an end-cell switch. In this case the number of cells in the main battery will be equal to the bus voltage divided by 2.1 and

the total number of cells in the battery will be equal to the bus voltage divided by the voltage per cell at the end of discharge for the discharge rate used. The difference between the number of cells in the main battery and the number of cells in the whole battery will be the number of end cells. These end cells can be connected to the points on the end-cell switch singly or in pairs, depending upon the voltage regulation desired. If it is not desired to maintain a constant voltage on an exciter bus, the end cells will not be required. The total number of cells will be kept on the bus bars and as the voltage of the battery falls the field excitation of the generators can be maintained constant by changing the generator field rheostats.

The ampere capacity of the cells will be determined by the amount and duration of the load to be carried. Knowing the ampere capacity, the length of time and the minimum allowable voltage during the period, the number of cells and the type of battery can be determined by the use of the charge and discharge curve and battery rating given in trade catalogues.

LINE BATTERIES FOR RAILWAY WORK. — (*See also Trolley Systems.*) The functions of a storage battery floating on an electric railway line at a distance from the power house are as follows:

1. To improve the line voltage and displace a certain amount of feed wire.
2. To relieve the power house of fluctuations of load.
3. To keep the cars moving when the power supply is temporarily interrupted.
4. To supply power for the operation of a few cars or lights at night when the power house is shut down.

Location. — Before any calculations can be made, the location of the battery must be decided. Where there are no other determining factors, the battery would ordinarily be located about three-quarters of the distance from the power house to the end of the line, or, if the line is fed from both ends, midway between the feeding points. In some cases the location of the maximum momentary load, due, for example, to a severe grade or to the passing of two cars at a siding, will influence the location of the battery. In other cases the location of a suitable piece of property owned by the company, or the location of a car barn where attendance would be available, may be the determining factor.

Line Battery without Boosted Feeder. — In this class of line-battery installation the number of cells is determined by the average line voltage at the proposed battery site on the basis of approximately 2.1 volts per cell. Thus, if the average voltage at the battery site, as determined by voltage readings taken at frequent intervals, such as five or ten seconds, over a considerable length of time, should be found to be 500 volts, the number of cells suitable for this average voltage would be 238. If it is found that, owing to changes in load conditions at different hours of the day or on different days of the week, the average voltage varies considerably for prolonged periods of time, it may be necessary to provide means for changing the number of cells connected to the line. This may be accomplished by separating a group of cells at one end of the battery, and arranging suitable switches so that these cells may be connected either in series with the main battery when the average voltage is high or in parallel with an equal number of cells of the main battery when the average voltage is low. It is found preferable to connect these end cells in parallel with a portion of the main battery, and thus keep them active rather than disconnect them from the system entirely.

Calculation of Size of Battery Required. — See article on *Trolley Systems, Overhead*, and *Bulletin No. 134* of The Electric Storage Battery Co.; also Chap. 44 of Lyndon's *Storage Battery Engineering*.

BATTERIES FOR SMALL CENTRAL STATIONS AND ISOLATED PLANTS. — The objects of a battery installation in small electric lighting and power plants may be any one or all of the following:

1. Twenty-four-hour service with but a few hours daily operation of engine.
2. Reduction in size of engine and dynamo otherwise required.
3. Improved voltage regulation.
4. A source of current during breakdown of machinery, or while repairs are being made.

Twenty-four-hour Service. — In this service the battery supplies the current during the hours when the engine is not running. As the capacity of a battery of normal size in many instances in this class of work, especially in residential service, is not generally exhausted in daily operation, it may usually be charged by running the engine and dynamo only two or three hours each day at the most convenient time. In summer, when the lighting hours are shorter, it may be sufficient to charge only once in two or three days.

Reduction in Size of Generator. — If the plant is so designed that the combined capacities of the dynamo and the battery are equal to the maximum load requirements, a smaller engine and dynamo may be installed than would be required if the dynamo alone had to carry the total maximum load. The battery will then be discharged in parallel with the dynamo, to assist it by taking a part of the total load on special occasions, as when the maximum number of lights is in use.

Improved Regulation. — Objectionable fluctuations of voltage and consequent flickering of lights, due, for example, to the operation of an electric elevator or other motor work, may be eliminated by floating the battery across the lighting bus.

Emergency. — In case of temporary derangement of the engine or dynamo, which may occur when the lighting service is most important, or in case repairs to the machinery are required, a battery will serve to tide over the break and avoid any interruption in the current supply.

Small Regulating Battery with Counter Cells. — Fig. 4 shows an ideal arrangement for small battery lighting plants where the capacity of the battery does not greatly exceed 300 ampere-hours at the normal rate. This figure shows 62 cells in the main battery with 8 counter cells, the whole being designed to operate on a 110-volt bus-bar. It will be noted that the battery is charged with two halves in parallel. During charge each half is placed across the bus-bars in series with a fixed resistance. At the beginning of charge the counter cells are all in circuit and assist the fixed resistances in reducing the bus voltage to the proper charging voltage. The counter cells are cut out of circuit as the battery voltage rises. On discharge, all of the cells in the main battery and the full number of counter cells are connected in series. As the voltage falls on discharge the counter cells are cut out of circuit, thus maintaining a steady voltage at the bus-bars. The number of cells and counter

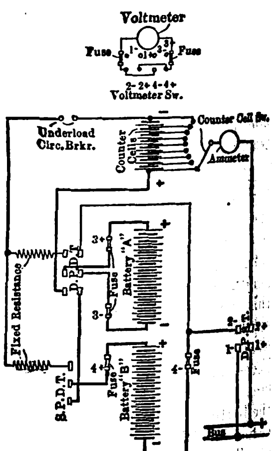

Fig. 4. Connections of Small Regulating Battery

cells shown in the figure are selected to maintain a steady voltage of 110 volts at the normal rate of discharge. The counter cells are composed of unformed battery plates or grids, and since they have very little active material they have practically no capacity. Each counter cell will, however, furnish an opposing voltage of approximately 2.3 volts; this counter voltage is practically constant over the range in current demand for an ordinary small station.

Small Regulating Battery with Charging Booster. — For larger-sized plants this method of operation is not economical owing to the loss in the charging rheostats and the loss in the counter cells. For a straight lighting plant where a battery of more than 400 ampere-hours capacity is required, it is usual to use the scheme shown in Fig. 5. It will be noted in this scheme that the cells in series are connected to the bus for discharge, the voltage being controlled by cutting in and out the end cells at one end of the series. On charge the required voltage to complete the charge is obtained by adding to the bus-bar voltage the voltage of a small booster generator.

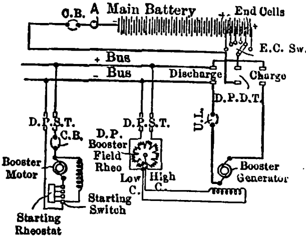

Fig. 5. Connections of Small Battery with Booster

Size of Battery. — For ordinary small plants which operate at a bus voltage of 110 the standard equipment consists of 64 cells, including 12 end cells. The capacity and type of the cells are fixed by the ampere-hour requirements and the minimum-voltage requirements on discharge. For any bus voltage other than 110 volts the complete number of cells, including the end cells, can be determined by dividing the minimum allowable bus voltage by the minimum voltage per cell at the end of discharge at the rate which will be used. The number of cells in the main battery will be equal to the bus voltage divided by 2.1. The difference between the number of cells in the main battery and the total number of cells will give the number of end cells. An end-cell switch having one point more than the number of end-cells required will be necessary.

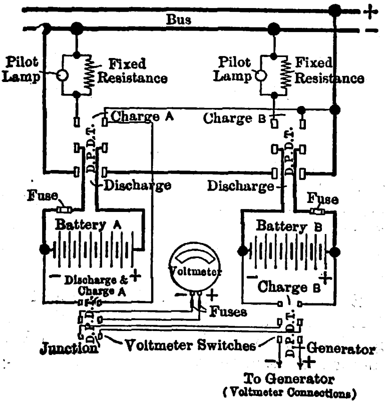

Fig. 6. Connections of Small Battery without Booster Cells

Small Battery without Voltage Regulation. — If voltage regulation on discharge is not required, the scheme shown in Fig. 6 can be used. It will be noted that this scheme is practically the same as shown in Fig. 4 except that the counter cells have been omitted and only 56 cells are used.

Small Battery on 3-Wire System. — In small central stations or isolated plants which utilize the 3-wire 110 to 220-volt system, the battery is arranged in two halves, one on each side of the neutral. A group of end cells on each side of the system and two booster generators direct con-

nected to one motor are used. This scheme of operation is shown in general in Fig. 1 which is described in detail above in the section on *Stand-by Batteries*.

Small Battery for Low-voltage Lighting. — Since the advent of the tungsten lamp, 32-volt plants for private residences and other small power plants are growing very popular. Fig. 7 shows a standard scheme utilizing a 32 to 42-volt generator, driven by a gasoline engine, and 16 cells of storage battery. It will be noted from the diagram shown that the lights can be carried entirely by either the battery or the generator, or by the battery and generator in parallel. It will also be noted that on charge the voltage of the generator is raised and three counter cells are placed in series between the generator and the lights, thus preventing excessive voltage at the lights.

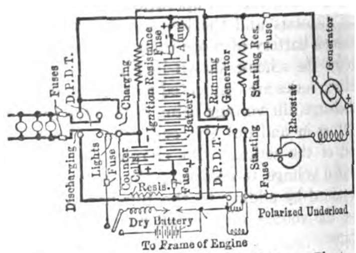

Fig. 7. Connections for Small Power Plant

Referring to Fig. 7 it will be noted that there is shown a polarized underload circuit breaker which is used for opening the circuit in case of trouble with the engine during charge. This is a reverse-current circuit breaker, which permits the current to drop to zero and even to reverse slightly before the circuit breaker will open. This provision avoids the difficulty of frequent opening of the breaker when the gas engine misses an explosion in normal operation. The polarizing coil is connected across the counter cells with a resistance in series for adjustment.

Current for ignition is taken from the terminals of the counter cells. The dry-battery cells shown are utilized for sparking the engine when the plant is first installed until the storage-battery cells have been charged.

The ignition resistance shown is for charging the counter cells whenever the dynamo is running. Ordinarily the engine ignition is obtained from the counter-cell circuit, the generator supplying the average current required and the counter cells acting as a reservoir.

The starting resistance shown in the diagram is used for starting up the engine from the battery. The generator is then used as a motor.

Size of Battery. — The proper type and capacity of cell will depend upon the requirements. It is customary to install a battery having a capacity at the normal rate sufficient to carry the ordinary lighting load for from 2 to 5 days. With a battery of this capacity it will be necessary to run the engine and generator only a few hours each day in order to keep the battery fully charged. Trade bulletins describing in detail these small plants can be obtained from the manufacturers.

SMALL REGULATING BATTERIES FOR ELEVATORS, ETC. — Fig. 8 shows a scheme of load regulation which has been adopted as standard for situations where it is desirable to operate a lighting load and a fluctuating motor load from the same generator. This scheme is known as the "constant-current" scheme.

Elevator Load Regulation. —This scheme finds its greatest use in office buildings, hotels, etc., where electric elevators are in service. The load on such a plant is a very fluctuating one on account of the heavy current required for starting the elevators. This starting current is generally about twice the elevator running current. Moreover, as the elevators are not in service con- ... less than the running

current per elevator. There is generally, therefore, a considerable difference between the average load on the station and the maximum momentary load. This difference varies with the number and type of elevators, the character of elevator service and the magnitude of the lighting load. If the fluctuations

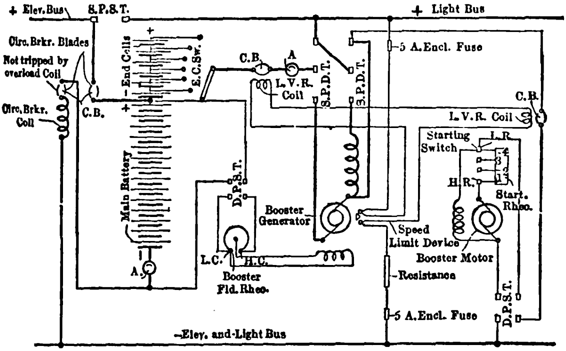

Fig. 8. Connections for "Constant-current" Regulation

above and below the true average are a comparatively large percentage of the true average load, they are liable to cause fluctuations in the generator voltage with consequent flickering of lights. In addition to this objection, the generating capacity necessary without a battery must be increased and it is necessary to operate the whole plant at a poor load factor.

Constant-current Scheme. — Reference to Fig. 8 shows that the battery and the elevator circuit are in multiple, and that the booster is in series between the lighting bus and the elevator bus. The booster in the constant-current scheme, as the name would imply, is wound in such a manner that the current going through it is rendered constant. Therefore, the parallel system of battery and elevator circuit can only draw a constant current from the generator, and it follows that all of the fluctuations due to the elevator load must be taken by the battery. When the elevator current is greater or less than the average, the difference is given or absorbed by the battery. It is important to note that the battery voltage applied to the elevator motors is that of the battery alone and is therefore variable. Ordinarily this is not a disadvantage as the heavy load is caused by the starting of motors, in which case high voltage is not an object.

It will be noted that the scheme given in Fig. 8 shows end cells. These are used for regulating the voltage on the lights when the generator is shut down and the booster is out of circuit, the battery carrying the entire lighting and elevator load.

Other Uses of Small Regulating Batteries. — Electric-elevator service has been taken as an example, as this is the class of work usually encountered. This scheme may be used, however, for other fluctuating loads, such as are due to electric cranes, shop tramways, mine hoists, etc., and in general for any fluctuating load where the maximum load is greatly in excess of the average load and constant potential on the motor bus is not required.

For fluctuating loads where constant potential on the power bus is required, the scheme described above under *Large Regulating Batteries* and shown in Fig. 2 should be used.

Number and Capacity of Cells. — The number of cells in the main battery is usually determined by dividing the bus voltage by 2.1. The number of end cells necessary will be determined by the minimum allowable voltage and the final cell voltage at the end of discharge when the battery is carrying the entire load. The capacity of the battery will be determined by the amount of the fluctuations to be taken care of by the battery and the amount of load to be taken out of the battery when the generating apparatus is shut down.

Booster. — It will be noted in Fig. 8 that the diagram shows a differentially-wound booster. The desired regulation is obtained by means of the series field, which carries the constant current between the lighting bus and the elevator bus, and which is designed to produce a booster voltage in the direction to oppose this current. The relation between the series field and the shunt field is adjusted for any given average load.

A straight shunt booster with the field controlled by the carbon regulator as shown in Fig. 2 can be utilized with this constant-current scheme, if the solenoid is connected between the lighting bus and the elevator bus and if the carbon regulator actuated by this solenoid is utilized to control the field of the exciter as shown in Fig. 2. In all other respects this carbon regulator constant-current scheme operates according to the same general principle as the scheme for the differentially-wound booster.

It will be noted also that with the scheme shown in Fig. 2 the booster is in series with the battery and carries only the battery current, whereas in the constant-current scheme shown in Fig. 8 the booster carries the average current of the fluctuating load. The relative magnitude of the fluctuations as compared with the average will determine which booster will be least expensive and may, therefore, be a factor in deciding between the two schemes.

Two- and Three-wire Systems. — The scheme shown in Fig. 8 is for a two-wire system. This same general scheme is utilized for a three-wire system where the motor load is connected across the outside wires and the lights are balanced on each side of the neutral. Where the three-wire system is used, the general principles of the scheme are exactly the same as shown in Fig. 8, except that it will be necessary to have one booster generator and one set of end cells on each side of the system.

ELECTRIC-VEHICLE BATTERIES. — The use of storage batteries for the propulsion of electric vehicles is increasing rapidly. The voltage and capacity of the battery necessary to operate any given vehicle is usually specified by the manufacturer of the vehicle, as the design of the vehicle determines the number of watt hours per car mile under certain definite conditions. Unless the vehicle user is a battery expert and a vehicle expert, it is not advisable that he specify either the number or capacity of cells to be used.

Desirable Characteristics of Vehicle Batteries. — The following are the chief characteristics of a good vehicle battery:

1. Low internal resistance, because of high current demand required for acceleration or for ascending grades.

2. Small capacity temperature coefficient, in order that the capacity of the battery shall not be unduly affected by chilling of the cells.

3. Voltage characteristic as nearly flat as possible under average conditions of discharge.

4. Construction of sufficient ruggedness to prevent breakage of parts in ordinary service.

5. Assembly such as to minimize possible labor and attention for flushing, cleaning, removing short-circuits, etc.

6. Ability to stand some abuse, as the average vehicle operator is not a battery

It is impossible for a battery to possess all these qualities to the same extent. With regard to the first three requirements the lead battery possesses peculiar advantages, whereas the Edison battery is superior in the last three features.

The use of batteries for vehicle work is treated in greater detail in the article on *Automobiles, Electric*.

DRAWBRIDGE BATTERIES. — It is becoming standard practice to install storage batteries in connection with electrically-operated drawbridges, chiefly as an insurance against the interruption of power from the generating station. The voltage of drawbridge motors is usually 220 or 500. The number of cells and the capacity of the cells to meet the requirements will depend upon the maximum and minimum allowable voltages, and the total energy required from the battery before recharging.

Size of Drawbridge Battery. — Assume a 2000-ton bascule lift bridge with a 185-foot span. This bridge is to be operated with 220-volt motors. The time required to open or close is 1½ minutes, or a total of 3 minutes for a complete opening and closing. Assume the following conditions: The battery will be required to open and close the bridge 40 times on one charge, the maximum allowable voltage during bridge operation will be 250 and the minimum allowable voltage 200; the average current demand over a complete cycle will be 100 amperes with a maximum momentary current demand of 320 amperes lasting a few seconds.

It is seen that the total energy in ampere hours required for the 40 complete openings and closings of the bridge would be equal to $\frac{3 \times 100 \times 40}{60} = 200$ ampere hours during a total period of $3 \times 40 = 120$ minutes or 2 hours. The battery, therefore, must have a capacity not less than 200 ampere hours at the 2-hour rate of discharge. Bearing in mind the voltage limits specified above, an inspection of Figs. 3 and 6 in the article on *Batteries, Storage, Lead Type*, will show that the battery capacity will be fixed by the voltage limits in this case and not by the ampere-hour requirements. In any case that may arise, if there is any doubt as to which requirement will fix the capacity of the battery, select a battery having the ampere-hour capacity required and then examine Fig. 6 to see if a battery having this ampere-hour capacity will meet the voltage requirements.

For a maximum allowable voltage of 250 and a floating voltage of 2.1 volts per cell, there would be required 120 cells. Referring to Fig. 6 and using the upper curves, for plates 10¾ inches square, we will assume that the battery must not discharge at a higher rate than 4 times the normal rate. At 4 times the normal rate the voltage drops almost immediately to 1.9 volts per cell. With 120 cells the voltage would drop to 228 volts. It is noted that the normal rate of this battery will be 80 amperes, and the average discharge of 100 amperes will be 1¼ times the normal rate. By interpolating a curve between the normal curve and four times the normal curve, it is seen that with an average discharge at this rate for 2 hours, the voltage per cell at the end of the two hours, with 100 amperes flowing, will be approximately 1.9 volts, or the voltage of the 120-cell battery will be 228 volts. If, now, the current were increased to 320 amperes (4 times the normal rate), and this current flow continued for an appreciable period of time, the voltage would drop further, by about 20 volts, leaving a voltage of 208 at the battery terminals. It is, therefore, evident that the voltage requirements will be met by a 120-cell battery having a capacity of 80 amperes at the normal rate.

A battery having a normal rate of 80 amperes could be discharged at 1¼ times the normal rate for something over 4 hours. It is, therefore, seen that the battery which we selected has more than ample ampere-hour capacity to

meet the requirements, its capacity being fixed by the momentary current demand.

It usually will be found that the capacity of cells required for drawbridge operation is fixed by the maximum discharge rate and not by the ampere-hour capacity at the average rate.

Size of Charging Generator. — If a separate power plant is installed for the operation of the drawbridge, it will be well to install an engine-generator set having an available voltage range of from 220 to 325 volts. There may be required 2.7 volts per cell for charge, which with 120 cells would call for 324 volts. If the battery installed is of sufficient capacity to carry the bridge a complete day or more on one discharge, it is good practice to install a generator of only sufficient capacity to charge the battery at the normal rate and to operate the bridge at all times from the battery. In the case cited above the capacity of the generator would be approximately 80 amperes. If it is required ordinarily to supply the bridge from the generator and hold the battery for emergencies, the generator must have sufficient capacity to carry the maximum current required by the bridge motors.

IGNITION BATTERIES FOR PORTABLE AND STATIONARY GAS ENGINES. — It is the usual practice with portable gas engines, automobiles, etc., to use for ignition a 6-volt portable battery put up in a wooden case. The capacity most frequently used is 60 ampere hours, though capacities ranging from 40 to 100 ampere hours are used, depending upon the requirements.

For stationary engines of large capacity it is customary to use a voltage ranging from 90 to 110 volts. Glass-jar batteries of sufficient ampere-hour capacity to meet the requirements are installed in a cabinet in the main engine room. The number of cells in the main battery necessary to float on the system will be equal to the bus voltage divided by 2.1. The capacity of the battery will depend upon the number of ampere-hours required on one charge and the minimum allowable voltage during a discharge. These requirements being known, the correct number and type of cells can be determined from the characteristics of the batteries (*see Batteries, Storage, Lead Type and Alkaline Type*), in connection with trade catalogues.

Occasionally, there is installed in addition to the cells in the main battery a group of end cells which can be cut in on discharge by means of a single switch and thus hold up the voltage of the battery. The number of cells in this end-cell group usually varies from 3 to 8, depending upon the voltage requirements.

Usually a large ignition battery is charged by placing the two halves in parallel, each half being connected to the bus through a fixed resistance somewhat after the fashion explained above and indicated in Fig. 6.

BATTERIES FOR STEADY-VOLTAGE REQUIREMENTS. — It is frequently required to obtain a source of direct current with a steady voltage, as, for instance, in electroplating, instrument calibration, telephone work, laboratory work, etc. In such cases there should be chosen a battery that has more capacity at the normal rate than the ampere hours actually required before recharging, in order that the battery may be worked on the flat portion of the discharge curve.

For instance, to furnish 10 amperes continuously for 8 hours at about 20 volts, with a variation of 1 per cent between the beginning and the end of the discharge, the time of discharge must be limited to about 50 per cent of the total time. A cell having a capacity of 10 amperes for 16 hours should, therefore, be chosen.

BIBLIOGRAPHY. — See Bibliography in article on *Batteries, Storage, Lead Type.*

[TALIAFERRO MILTON.]

BATTERIES, STORAGE, LEAD TYPE. — (*See also Batteries, Storage, Applications of; Batteries, Storage, Alkaline Type; Electrochemistry, Principles of.*) The following is a brief outline of the contents of this article:

TYPES OF LEAD CELLS. — A secondary or storage cell is any voltaic couple which can be regenerated, after exhaustion, by passing a current through it in a direction opposite to the direction of current flow when the couple delivers energy to the external circuit. Three types of storage batteries are now in use in this country, the Planté type, the Faure type, and the alkaline or Edison type. The special features of the alkaline type are treated in a separate article, viz., *Batteries, Storage, Alkaline Type.*

Planté Type. — The principle of the storage battery was discovered in 1801 by Gautherot, a Frenchman. However, practically nothing further was done until 1860 when Gaston Planté constructed a storage cell consisting of two lead strips immersed in dilute sulphuric acid. Planté found that, by giving this cell a long charge by passing the current through in one direction, and then giving the cell a long charge in the opposite direction, and repeating this cycle many times, the capacity of the cell was considerably increased. Little improvement was made in the Planté cell until a number of years after Planté's discovery.

At present the Planté type of storage battery is made by preparing a pure lead plate with a large superficial area exposed and then oxidizing the surface electrolytically so that it is covered with lead peroxide. A plate formed thus is a positive plate. To form a negative plate the peroxide, after electrolytic formation, is reduced to metallic sponge lead by reversal of current. In this manner a thin layer of active material which is porous and which adheres firmly to the supporting lead plate is produced.

Use of Planté Type. — The Planté type is used chiefly where weight and space are of no great importance.

Faure or Pasted Plate. — In 1880 Camille A. Faure, in France, and Charles F. Brush, in America, simultaneously developed the "pasted" type of storage battery. In this type of storage battery the active material, on both the positive and negative plates, instead of being formed electrolytically, as was done by Planté, was applied, in the form of a paste, to a stiff lead-antimony alloy supporting grid. This type of plate is now commonly called the Faure type of plate, and it was the discovery of this type that gave the storage battery its first commercial impetus.

Use of the Faure or Pasted Plate Type. — The Faure type is used chiefly where it is desired to obtain the greatest possible capacity with a minimum of weight and space occupied. This type is used chiefly for vehicle propulsion and for central-station "stand-by service."

THEORY. — The electrochemical theories of the storage battery are quite complicated and the various authorities on these subjects do not agree on all details. In this outline no attempt will be made to cover the various theories in detail; only the simplest fundamental chemical actions will be described.

Positive and Negative Plates. — The terms positive and negative are employed throughout this article in accordance with engineering usage; that is, the positive plate is the one from which the current flows on discharge and the negative plate is the one into which current flows on discharge. In a lead battery the positive plate, on which the lead peroxide is formed, has a comparatively hard surface of a reddish-brown or chocolate color, while the negative plate, which carries the sponge lead, has a much softer surface of a grayish color.

Chemical Reactions. — The active elements of the lead-lead acid type of battery consist of lead peroxide (PbO_2) on the positive plate, sponge lead (Pb) on the negative plate and dilute sulphuric acid (H_2SO_4) for the electrolyte.

Whatever the secondary reactions may be, it is agreed that the final result on discharge is the formation of lead sulphate ($PbSO_4$) on both the positive and negative plates, the SO_4 radical of the sulphuric acid combining with the lead of both plates to form this compound, resulting in the formation of some water (H_2O), with a consequent decrease in the specific gravity of the electrolyte. On charge the electric current splits up the lead sulphate ($PbSO_4$), returning the SO_4 radical to the electrolyte, oxidizes the positive plate to its original condition of lead peroxide (PbO_2) and reduces the negative plate to its original condition of sponge lead (Pb). This action may be represented as follows:

$$\underset{+\text{ Plate}}{PbO_2} + 2\,H_2SO_4 + \underset{-\text{ Plate}}{Pb} = \underset{+\text{ Plate}}{PbSO_4} + 2\,H_2O + \underset{-\text{ Plate}}{PbSO_4}$$

This equation read from left to right is the equation of discharge; if read from right to left, it is the equation of charge. In practice, on charge, towards the end of charge some of the water (H_2O) is split up by the current into its component parts, hydrogen (H) and oxygen (O), the hydrogen being liberated at the negative plate and the oxygen at the positive plate. This occurs whenever the density of charging current is greater than can be utilized in decomposing the lead sulphate remaining in the plates.

DESIGN. — The capacity of a storage-battery plate depends not only upon the amount of active material but also upon the active surface exposed to the electrolyte. Plates should therefore be designed to expose a maximum amount of surface consistent with the strength of the supporting grid or lead base. In order that the active material of the plates can be acted upon by the electrolyte, it should be as porous as is consistent with its proper support by, and proper contact with, the grid or supporting lead base.

Sponge lead and lead peroxide possess little mechanical strength. Lead peroxide is a poor conductor. Since mechanical conditions require a certain amount of rigidity in the plates and since the current generated by the active materials must be carried away, a battery plate must necessarily consist of two parts, viz., the grid or supporting base and the active material which in the lead battery is finely-divided porous sponge lead or porous lead peroxide, and in the alkaline battery is finely-divided nickel and nickel hydroxide in the positive plate and iron oxide in the negative plate.

Lead Plates. — There are certain ideal requirements to be met by a lead storage-battery plate, among which may be mentioned:

1. The grid and active material should be so proportioned as to obtain, as far as possible, uniform current distribution over the entire surface.

2. The active material should be applied to, or formed on, the grid in such a manner that good electrical contact exists when the plate is new and this contact should be maintained during the life of the plate.

3. In pasted plates and pellet plates the grid should be of material that is not injuriously affected by the electrolyte.

4. The material of the grid should be such as to insure a minimum of local action between itself and the active material.

5. The surface of the active material exposed to the action of the electrolyte should be as great as is compatible with proper mechanical strength and a suitable provision for the natural expansion of the active material in use.

6. The plates should be so made and assembled as to allow the maximum possible diffusion of the electrolyte through and around the plates and through the containing vessel.

7. The grid or lead base should be of ample cross section to carry the current generated under working conditions without undue loss.

8. The lugs which collect the current from the grids should be of ample cross section, and when designed for heavy currents they should be so arranged as to distribute the current uniformly through the grid.

9. The negative, sponge-lead plate should be constructed so that the sponge lead retains its porous character and does not grow hard and dense in service and thus lose its capacity.

10. The lead and the electrolyte should be pure; otherwise secondary reactions will be set up, with a consequent decrease in efficiency.

Of the many lead plates on the market to-day, the most commonly used are the "pasted," Planté and composite or "pellet" plates. Cuts showing the construction of the various types of plates may be found in manufacturers' catalogues; the essential features of design are briefly discussed below.

Pasted Plates. — The pasted plate is usually made by applying to a hard lead-antimony grid a paste made of some oxide of lead, usually litharge (PbO) or red lead (Pb_3O_4), and some liquid and other substances. In the so-called "Iron-clad" battery made by the Electric Storage Battery Co., the active material is held in perforated hard rubber tubes. Various substances are used to mix with the lead oxide, the idea being to increase the hardness, porosity, toughness and conductivity. Some of the substances used by different manufacturers include anthrocine, glycerine, graphite, potassium silicate, asbestos, ammonium-sulphate, etc.

"Forming" of Pasted Plates. — After the grid is filled with the paste, the plate is dried. After being completely dried a number of plates are assembled in a forming bath of dilute sulphuric acid with dummy lead plates for the opposite electrode and the forming charge is given by passing the proper current through the voltaic couple thus formed. Positive plates are formed by connecting the plates to be formed as the anode; the current oxidizes the lead oxide further to lead peroxide (PbO_2). Negative plates are formed by passing the current in the opposite direction, reducing the lead oxide to sponge lead. After the forming charge the plates are dried and are ready for the market.

Planté Plates. — Of the various types of Planté plates, among those most commonly in use may be mentioned the central-web type; the cast-lead having no central web; and the composite or "pellet" type. The main idea in any of these methods of manufacture is to produce a large surface on which to form the active material.

Central-web Type. — In the central-web type there is a solid sheet or "web" of pure lead on which the ribs are formed. This web prevents the circulation of the electrolyte through the plate. The ribs are formed from the original lead plate, either by rolling, spinning or cutting. In the rolling and spinning processes the plate is formed from a lead blank by means of a number of steel disks placed side by side and separated by small spacers on a shaft. The lead blank is passed between two sets of disks by forward and backward movements. The disks gradually work deeper into the plate and squeeze up

lead into the spaces between the adjacent steel disks. In the cut type of plate the ribs are formed from the lead sheet by a tool, which at each stroke turns up one complete rib. The cutting edge works at an angle so that the finished ribs stand out from the surface. The ribs may incline upward from the central web and thus form pockets to hold the active material and prevent its falling away.

The disadvantage of the *web* type is the web itself. There is invariably a tendency towards unequal work on the two sides of the positive plate, this tendency being caused by difference in the plate spacing, unequal capacity of the negative plate on either side, inequality in the shape of the ribs, etc. Where the active material and the active surface of a plate are disposed in planes perpendicular to the face of the plate and extend *through* the plate, excessive action on one side simply works the plate a little further through from that side, the effect on the active material, however, being uniform throughout. With a plate provided with a central web, preventing such action, any inequality of work will charge or discharge one side more than the other, producing a tendency to buckle.

Cast-lead Type. — The type of plate which has no central web is made by casting pure soft lead in a mold, casting having the advantage of allowing for distributing metal in the plate without limitations in manufacturing process. The plate as it comes from the mold consists of a great number of short vertical ribs running entirely through the plate and bound together by transverse ribs to give strength to the plate. In this manner a large surface can be obtained and in a plate having no central web the electrolyte can circulate through the plate, and the active material will be uniformly worked throughout even though the amount of work on the two sides of the plate be unequal. The best-known form of this plate is the "Tudor" positive.

Composite or "Pellet" Type.— The composite or pellet-type plate is made by rolling up into pellets pure soft-lead corrugated ribbons. These pellets or buttons are then forced by pressure into circular openings in a grid composed of a hard-lead-antimony alloy. The openings in the grid are beveled towards the center so that when the pellets are formed the swelling action causes them to rivet tightly into place. The corrugations on the lead ribbon allow the electrolyte to circulate through the plate and thus expose the full surface of the closed lead spiral to the action of the electrolyte. It will be noted that in this type of plate additional mechanical strength is obtained from the supporting grid. The best-known form of this plate is the "Manchester" positive.

"Forming" of Planté Plates. — In all Planté positives, after the ribs or corrugations have been formed on the lead blank or the pellets have been placed in the hard grid, the plates are assembled in a sulphuric-acid bath containing some corrosive chemical, called a "forming agent," together with dummy lead plates. The forming agents used by various manufacturers are usually kept as trade secrets; the nature and method of using such agents determines largely the quality of the battery. To form the positive plates the dummies are connected as the cathodes, and a current is passed through the couple thus formed. The electrolytic action of this current causes lead peroxide (PbO_2) to be formed from the lead of the ribs. The strength and duration of the current produce the desired thickness of lead peroxide on the ribs or pellets.

Negative Planté plates are made from positive plates by electrolytically reducing the lead peroxide to sponge lead. In most types of Planté negatives, however, it is necessary to form them with an initial capacity considerably in excess of the capacity of the positive plate. This is due to the fact that in actual service the sponge lead shrinks and loses its spongy nature, thereby reducing its capacity, since insufficient surface is exposed to the action of the

"Permanizing" Process. — One of the large manufacturers of storage batteries has recently developed a process for making the Planté negative plate permanent. This method consists of injecting into the sponge lead a material which prevents the shrinking of the sponge lead and thus enables it to maintain its spongy character and its initial capacity. This permanizing process can be applied to the pasted negative plate as well as to the Planté negative plate. The most widely used form of the permanized negative plate is one in which the sponge lead, formed by reducing lead oxide electrolytically, is retained in boxes made by casting a soft-lead perforated sheet on a hard lead-antimony grid. This negative is known as the "Box negative."

Applications of the Various Types of Plates. — In stationary work requiring frequent discharges, where expert attention is available at all times, and where the conditions of operation are properly suited to its use, the all-lead Planté type of plate with through-and-through circulation is the plate that should be used. Where the battery is to receive little attention and where the conditions of service are variable and uncertain, the composite or "pellet" type of plate is the safest plate to use, on account of its rugged structure and its ability to stand great abuse. As stated above, for stand-by service and for vehicle service and other service where high capacity with a minimum weight and space is desired, the pasted type of plate is more desirable.

Electrolyte. — The electrolyte used with the lead type of battery is always a dilute solution of sulphuric acid. The specific gravity of the electrolyte, when the battery is fully charged, varies from about 1.210 for stationary batteries to 1.300 for automobile ignition batteries. These values have been adopted as standard by all the leading manufacturers.

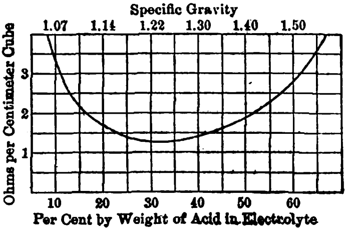

Fig. 1.

The proper specific gravity to use varies with the conditions. Fig. 1, showing the variation with specific gravity of the resistance of one cubic centimeter of electrolyte, shows that the resistance of dilute sulphuric acid is least at a specific gravity of from 1.224 to 1.240, this resistance increasing if the specific gravity be either increased or decreased. There are numerous other conditions which influence the selection of the proper specific gravity.

The curves in Fig. 2 show the specific gravity of various mixtures, both by weight and by volume, of one part of 1.840 specific gravity acid with from 1/10 to 7 parts of water. There is also a curve showing the percentage, by weight, of 1.840 specific gravity acid in mixtures of various specific gravities. These curves are approximately correct at 60° F. Unless a compensating hydrometer is used in determining the specific gravity, allowance must be made for temperature variation, on the basis of an increase of one point (i.e., one one-thousandth) in gravity for each 3 degrees Fahrenheit *decrease* in temperature, and vice versa; for instance, electrolyte that has a specific gravity of 1.210 at 70° F. will have a specific gravity of 1.213 at 61° F., and 1.207 at 79° F.

Impurities in Electrolyte. — The electrolyte should be free from organic substances, iron, chlorine, copper, arsenic, mercury, nitrates, acetates and the slightest possible trace of platinum. The various battery manufacturers issue exact specifications to the acid manufacturers, specifying the maximum amount of these injurious ingredients which the acid may contain. Electrolyte that is not approved by the company furnishing the battery should never be used.

Preparation of Electrolyte. — In preparing the electrolyte, sulphuric acid, approved by the battery manufacturer, should be diluted with sufficient pure distilled water to bring the mixture to the required specific gravity. The acid should be poured into the water; *never pour the water into the acid.* If the water is poured into the acid, the heat formed by the mixture is sufficient to cause sputtering and damage may ensue.

The sulphuric-acid manufacturing companies furnish electrolyte for battery work in such large quantities that they carry a stock of various standard mixtures. It will usually be found cheaper and more convenient to purchase the electrolyte ready-mixed than to purchase the concentrated sulphuric acid and prepare the mixture on the ground. The latter course, however, is sometimes adopted where the amount of acid used is considerable and where the item of freight saving is appreciable.

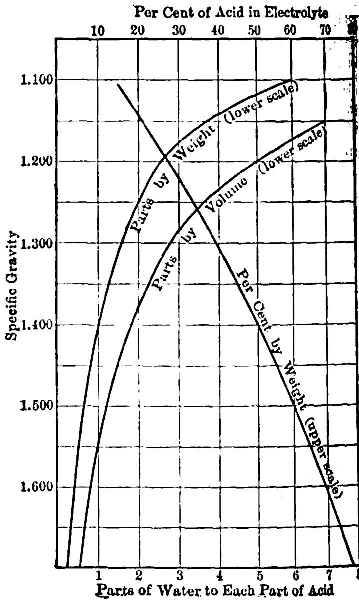

Fig. 2.

Containers for Lead Batteries. — The containing receptacles for holding the battery plates and electrolyte are usually rubber jars, glass jars or lead-lined wooden tanks.

Rubber Jars. — Hard-rubber jars are used exclusively in vehicle and portable batteries. In these batteries the plates are supported on ribs at the bottom of the jars. To reduce cleaning to a minimum, these ribs should be of sufficient height to leave ample space in the bottom of the jar for the reception of the active material which falls away from the plate. If the sediment in the bottom of the jars is allowed to reach the plates and short-circuit them, serious damage will result. The jars themselves should be made of the very best hard rubber which is not affected by sulphuric acid.

Glass Jars are ideal containers for small batteries when they are properly installed. The glass jar has the advantage that the plates and electrolyte can always be seen. The use of the glass jars is limited to the smaller sizes on account of their liability to break, due to strains left in the glass after annealing, temporary strains set up by unequal temperatures between the inside and outside of the jars, and to strains due to weight of the plates and electrolyte. Glass-jar manufacturers have, up to the present time, been unable to produce a thoroughly reliable jar larger than 21 by 13 by 18 inches.

Lead-lined Tanks. — In the larger sizes of batteries lead-lined tanks are standard. Tanks are generally made from specially selected yellow pine, dovetailed together without the use of nails or other metallic fastenings. The upper edges should be slightly beveled inward so that the moisture will drain

lated; these bottoms are usually constructed of slats across the tanks, separated by a small spacing to provide drainage. To further facilitate drainage under the lining, the upper surface of these slats should be grooved crosswise. Before the tanks are lined they should be coated inside and outside with two coats of acid-resisting paint, and a third coat should be added outside during installation. The tanks should be lined with lead of 3 to 4 pounds per square foot, depending on their size. The lining should extend over the upper edge of the tank and a short distance down the sides. The outer edge of the lining should be provided with drip points projecting clear of the tank, so that any drip from the lining will clear the wood of the tank and the tank supports. Especial attention should be paid to the seaming of the linings. All seams should be burned with the hydrogen flame with pure lead, without the use of any flux. The lower corners of the lining should be reënforced by puddling with lead. The upper corner should be reënforced by burning on an additional thickness of sheet lead. Each tank should be so built that it is self-supporting without the use of any braces or reënforcements. If this is done, any tank in the battery can be removed and replaced without affecting the remaining tanks in any way. A poorly constructed wood tank is bound to cause trouble. Special attention should be paid to this detail in preparing specifications.

Covers. — While covers are not absolutely necessary for stationary batteries, it is considered good practice to cover all cells. Covers should preferably be made of glass of sufficient weight to prevent excessive breakage in handling. Covers will more than pay for themselves in reducing evaporation and keeping out dirt. They are absolutely necessary in situations, such as steel mills, where the air is liable to contain particles of foreign matter injurious to the battery.

Support of Plates in Container. — As stated above, in the portable and vehicle types of batteries, the plates are supported on ribs at the bottom of the jar.

In stationary types, using glass jars or lead-lined tanks, it is preferable to support the elements from the top. In glass jars, plates are supported on the top edges of the jars by means of lugs cast or burned on to the plates. In lead-lined tanks it is, of course, necessary to insulate the plates from the lead lining. The plates are, therefore, supported in the tanks by vertical sheets of glass resting on the bottoms of the tanks. The bottom of the tank lining, under the glass sheets, should be heavily reënforced. These glass sheets should be ground top and bottom and the lower corners should be cut off at an angle of about 45°, to avoid injury to the lead lining during installation by sharp corners.

Separation and Separators. — Since the positive and negative groups, forming the complete element in a cell, are assembled with positive and negative plates alternating, it is necessary that some means be provided to prevent contact between adjacent positive and negative plates. Such contact would mean a short-circuit and might result in injury to the element. Various forms of separators have been used for keeping the plates apart. The most common practice to-day, and the one considered the best for stationary work, is to use wooden diaphragms. Each wooden diaphragm should consist of a thin sheet of porous wood mounted in slotted dowels which will allow free passage of the electrolyte between the plates. The wood should be specially treated to insure the absence of elements which in conjunction with the electrolyte might form acids injurious to the plates.

In vehicle batteries rubber separators are generally used in addition to the wood separator. That is, a rubber separator is placed on each side of each positive plate and one wood separator between each positive plate and the adjacent negative plate. In the so-called "iron-clad" battery, made by the

Electric Storage Battery Co., the active material of the positive plate is contained in rubber tubes, and therefore additional rubber separators are not necessary. Ignition batteries use wood separators only. Portable batteries use rubber only. Car-lighting batteries use wood only or rubber only. Yacht-lighting batteries use rubber only.

Sediment Space. — In all types of batteries, no matter what container is used, there should be a certain amount of free space between the bottoms of plates and the bottoms of jars. This space is designed to receive the sediment or active material which falls away from the plates. The amount of sediment space required will depend upon the service, and no fixed rule can be given to cover this point. If not prohibitive from space or expense limitations it would be well to have this sediment space great enough to take all of the active material which will be shed from the plates during their useful life.

Assembly of Parts. — All portable, automobile, car-lighting and other batteries that will be subject to jar or vibration should be assembled in the containing vessel in such a manner that the plates cannot move. They should be packed in as tightly as is possible with due consideration to the amount of electrolyte necessary and the avoidance of injury to the plates when being put into or taken out of the jars. Hard-rubber covers should be used and these covers should be so sealed as to avoid any splashing of the electrolyte. The crates containing the jars should be constructed, as far as possible, without the use of metallic fasteners and they should be thoroughly painted with acid-resisting paint. In portable batteries that will receive rough handling, if several jars are assembled in a single crate, they should be imbedded thoroughly in an acid-proof elastic compound.

Cells assembled in crates should be connected by burning together the adjacent positive and negative terminals. Cell connections should never be soldered. The main terminals of the series in one crate should be brought out and fastened in such a manner that these terminals will not be attacked by the acid.

The methods of assembling and connecting stationary types of cells are described below in the section on *Installation*.

METHODS OF TESTING. — The tests described below are intended to cover only those tests that are of interest in the commercial operation of batteries.

Test of Specific Gravity. — The specific gravity of the electrolyte is the most accurate guide as to the state of charge of a lead-type storage battery. Specific instructions furnished by the manufacturer of the battery are given, showing the range in specific gravity over a given amount of charge and discharge and the operator should be guided by the instructions of the manufacturer. The test of the specific gravity is made by means of a hydrometer having a suitable scale for the type of cell to be tested. In stationary types of batteries the hydrometer has a scale reading of 1150 to 1250 and is left floating in one cell. In all portable types of batteries, and ordinarily in vehicle- and car-lighting batteries, it is usually necessary to draw some of the electrolyte from the cell in order to test its specific gravity with the hydrometer, which should have a scale reading of 1150 to 1300. Hydrometer syringes, with hydrometer contained in a glass barrel, can be obtained on the market for this purpose. There is also on the market a regular acid-testing set consisting of a syringe for withdrawing the acid and a test tube into which the acid is poured from the syringe, in order that the hydrometer may be floated for reading.

Test for Impurities in Electrolyte. — The proper testing of electrolyte for impurities requires not only some knowledge of chemistry, but also experience

for the ordinary user to attempt it. Furthermore, it is usually entirely unnecessary that he should, since the leading battery manufacturers make analyses for their customers free of charge. The harmful impurities most likely to be present are iron, hydrochloric acid, oxides of nitrogen, sulphurous acid, arsenic, organic matter and platinum. In order to insure freedom from the latter, it is advisable to specify acid which has not been concentrated in platinum.

Test of Internal Resistance. — The most accurate method of determining the internal resistance of a cell is to subject it to a discharge current of a certain amount, and after the voltage has become sufficiently constant to permit accurate reading with the discharge current flowing, the current is instantly interrupted and the rise of voltage noted. This rise of voltage divided by the current will give the internal resistance. If this test is made on a battery of more than one cell in series the result shows the internal resistance of the entire battery, including the cell connections.

Test of Capacity. — The capacity of a storage cell depends on various conditions, such as the temperature, the rate of discharge, the strength of the electrolyte, the character of service to which it has previously been subjected and the attention it has received. The "normal capacity" of a storage cell is usually expressed in ampere hours at the 8-hour rate at 70° F., down to a certain definite voltage per cell. For instance, when it is said that a cell has a capacity of 100 ampere hours, it is *usually* meant that this cell can be discharged at a rate of 12½ amperes continuously for 8 hours at 70° F., down to the limiting voltage specified by the battery manufacturer. In lead cells this limiting voltage is usually taken at 1.75 volts per cell. The "watt-hour" capacity of a battery is equal to the ampere-hour capacity multiplied by the average voltage during discharge.

The "available" ampere-hour and watt-hour capacity of a battery varies with the rate of discharge, the available capacity decreasing with increase of rate. The higher the rate of discharge the lower the limiting voltage at end of discharge. Therefore, to test the capacity at any given rate of discharge, the limiting voltage at that rate as specified by the manufacturer should be known.

Bearing in mind the above facts, to test the capacity of a storage battery at any given rate, the battery should be first charged at the normal rate, as specified by the manufacturer, until the voltage and gravity in all of the cells will rise no further and until all cells gas freely at both the positive and negative plates. The capacity of the battery, as a whole, will be limited by the capacity of the lowest cell and all cells should be as nearly as possible in a condition of full charge before the discharge is started to test the capacity of the battery. Individual cell readings should be taken of the voltage and gravity while the charging current is flowing.

When it is certain that the battery is fully charged, discharge the battery at a constant current at the desired rate, down to the limiting voltage at this rate. The ampere-hour capacity will be equal to the constant current in amperes, multiplied by the time of the discharge in hours; and the watt-hour capacity of the battery will be the ampere-hour capacity multiplied by the average voltage during discharge.

In order to be sure that the battery is in good condition it is well to take several complete discharges before making the final charge, preceding the final test discharge.

On each charge and discharge observations should be taken of the voltage, the current, the temperature and the specific gravity. The temperature of the room should be held as nearly constant as possible throughout the test. In order to facilitate the plotting of curves, the readings should be taken at intervals of time which are even factors of an hour.

Cadmium Test. — When a strip of cadmium is placed across the top of the plates in a cell, and properly insulated from them, there will be a difference in potential, as measured by a voltmeter, between the cadmium and the positive plates and between the cadmium and the negative plates; the sum or difference (depending on the relative directions of the two potential differences) between these two readings being equal to the internal voltage of the cell.

Such a test, when properly interpreted, is a valuable guide to the capacity and condition of the positive and negative plates separately. The results are, however, very apt to be misleading to one who has not had a wide experience in storage-battery work.

Test of Efficiency. — The ampere-hour efficiency of a battery is the ratio of the output on discharge in ampere-hours to the input on charge in ampere-hours; the watt-hour efficiency of a battery is the ratio of the output on discharge in watt-hours to the input on charge in watt-hours.

The efficiency of a battery depends upon numerous conditions, chief among which are the charge and discharge rates and the temperature.

It has been noted above that the *available* capacity of a battery depends upon the discharge rate. For instance, if a battery is discharged at the one-hour rate to the allowable final voltage limit, the energy taken out at this rate is approximately only fifty per cent of the energy that could be taken out at the normal rate. However, if, at the end of one hour's discharge at the one-hour rate, the rate of discharge be reduced to the normal rate, much of the available *normal* capacity of the battery can be obtained.

It is thus seen that any statement of the true efficiency of a battery should include the charge and discharge rates. It is also seen that in order to make a true efficiency test an average of several charges and discharges should be taken, and the battery should be given several discharges and charges before the actual test is begun. Failure to observe these conditions may result in figures that are misleading. The writer has seen test figures showing an efficiency of more than one hundred per cent; he has also seen figures showing efficiencies far below the actual efficiency.

To determine the efficiency of the battery, get all the cells in satisfactory condition by preliminary charge and discharge, as outlined above under the capacity test, and then take a preliminary discharge down to the final voltage specified by the manufacturer for this rate of discharge. The first test charge should then be made at the normal rate until the cells are fully charged. The first test discharge should then be taken at the specified rate down to the same final voltage used in the preliminary discharge. The watt-hour efficiency of the battery will then be the ratio of the total watt-hours discharged to the total watt-hours charged. If greater accuracy is desired, this cycle should be repeated several times (say, from four to six times) and the watt-hour efficiency will then be the ratio of the total watt-hours of all the discharges to the total watt-hours of all the charges.

RATING AND PERFORMANCE. — The capacity of a storage-battery plate of a given size varies somewhat with the conditions, chief among which are the specific gravity of electrolyte, the temperature of electrolyte, the amount of electrolyte, the original formation of the plate, the design of the grid, the age of the plate, the length of time between charge and discharge and the final voltage limit specified.

Rating of Stationary Batteries. — The rate of discharge of a storage battery is the number of amperes that it will supply continuously for 8 hours, for 3 hours or for 1 hour. The 8-hour rate is the so-called "normal" rating, the 3-hour rate is approximately twice the normal rating and the 1-hour rate is approximately 4 times the normal rating. The *capacity* of a storage battery is usually

stated in ampere hours. Since the capacity varies with the rate of discharge, it is necessary to specify the rate of discharge in stating the capacity in ampere-hours. If the rate is not specified, the normal rate is assumed.

Certain plates especially designed for high rates of discharge are rated in terms of the amperes they will supply for 6 hours, this rating being designated as "normal." The corresponding 1-hour rate is 4 times this 6-hour rate.

While the above is standard for ordinary batteries, plates for certain classes of service are designed to give the normal rate for from 7 to 7½ hours.

The capacity of a storage battery is sometimes expressed in kilowatts, but this is ambiguous unless the rate of discharge is specified.

Rating of Vehicle and Ignition Batteries. — It is standard practice to rate a vehicle battery in terms of the amperes it will give continuously for 4, 4½ or 5 hours, specifying the battery to have a capacity of so many ampere-hours at one of these rates. In most portable types of ignition batteries the batteries are rated at so many ampere-hours at the "service rate," i.e., the rate of discharge (amperes) corresponding to the service for which they are designed.

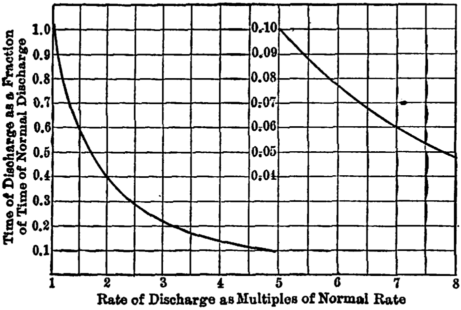

Fig. 3.

Variation of Rate of Discharge with Time of Discharge. — Fig. 3 shows an average capacity curve for a Planté plate, the time for a complete discharge at any rate being shown as a fractional part of the normal time and the rate of discharge for any given time being shown as a multiple of the normal rate.

From these curves it will be noted that a cell which will give its normal rate for 8 hours will give 4 times that rate for about 1⅛ hours; and a cell which will give 4 times the normal rate for 1 hour will give the normal rate for only 7 hours. These are approximately correct relations for the average Planté cell. Trade catalogues usually specify the normal rate for 8 hours and 4 times the normal rate for 1 hour. This is due to the fact that a cell which is regularly worked at the normal rate will tend to hold its 8-hour capacity, while a cell which is regularly worked at 4 times the normal rate will tend to lose some of its 8-hour capacity and finally give only 1 hour at 4 times the normal rate.

Variation of Capacity with Rate of Discharge. — It will be noted from the capacity curves that the available capacity in ampere-hours decreases with increase of rate of discharge. This is largely due to the time required for fresh electrolyte to penetrate into the pores of the active material of the plate. At the higher rates of discharge the diffusion of electrolyte is not sufficiently rapid to reach the more remote portions of the active material, and these portions are not fully available at these high discharge rates. As should be expected, if, after all of the available capacity at any given rate has been delivered

by the battery, the battery be allowed to rest or the rate of discharge be decreased, additional capacity can be obtained from the battery.

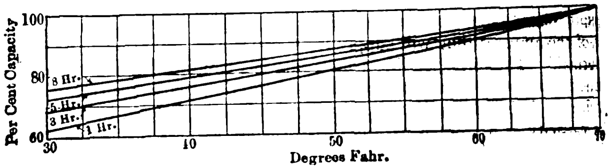

Fig. 4.

Variation of Capacity with Temperature. — Fig. 4 shows the variation of capacity with temperature at various rates of discharge. This change of capacity is temporary and the capacity will be restored to its original value when the temperature is restored to its original value.

Voltage and Specific-gravity Characteristics. — The charge and discharge voltage characteristics of a battery vary with the conditions. Fig. 5 shows typical average voltage and specific-gravity charging characteristics of a Planté type of cell designed for stationary service. It will be noted that the specific gravity increases gradually until all of the lead sulphate in the plates has been reduced, the (SO_4) radical being returned to the electrolyte to form sulphuric acid, which accounts for the steady increase in specific gravity and for the fact that the specific gravity will rise no further after the battery is completely charged.

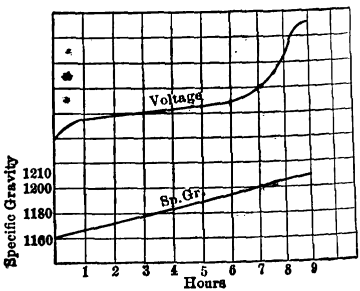

Fig. 5.

Final Charging Voltage (Fig. 5). — The scale of volts on the upper curve has been purposely omitted, but this curve shows the general shape of charging curve for any type of lead battery. The final charging voltage of any lead type of battery varies over a considerable range, according to the type of cell, age of plates, temperature of electrolyte, strength of electrolyte, etc. The final charging voltage may vary anywhere from 2.4 to 2.8 volts per cell. It will be noted that the voltage rises rapidly at the beginning and at the end of charge.

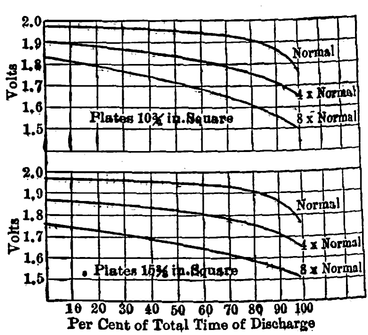

Fig. 6.

Discharge Voltage. — Fig. 6 shows discharge curves at the normal, four times the normal and eight times the normal rates, respectively, for two different sizes of Planté plates The upper set of curves are for plates 10¾ inches square and the lower set of curves are for plates 15¾ inches square.

These curves, used in conjunction with the capacity curves shown in Fig. 3, will enable anyone to determine the approximate performance of any lead battery when the capacity at any given rate is known.

The voltage readings at the very beginning of the discharge are liable to vary more or less from those shown on the curves depending upon the length of time the cell has been allowed to stand on open circuit after the completion of the charge.

Open-circuit Voltage. — The open-circuit voltage of a lead cell is of no value as an indication of its state of charge. A healthy cell will regain its full voltage on open circuit, even though fully discharged, if sufficient time is allowed for depolarization.

Internal Resistance. — The true internal resistance of a cell may be determined by the method explained above in the paragraph on *Test of Internal Resistance*. This internal resistance determines the *immediate* change of voltage at the cell terminals with any sudden change of discharge rate. In the ordinary commercial types of lead cells at 70° F. the internal resistance is such as to cause an immediate drop in terminal voltage of between 5 per cent and 7 per cent, with a sudden increase of current equal to four times the normal rate of discharge, the drop being proportional to the change in current. If this change in current is not strictly momentary, the change in terminal voltage will be greater, due to the effect of polarization. The internal resistance of a cell increases with reduction of temperature; at 0 °F. the internal resistance is twice as great as at 70° F.

DIMENSIONS AND WEIGHTS. — In determining the dimensions and weights of a storage battery to meet the requirements, it is suggested that the proper type of battery be determined in accordance with the curves and examples given above and a battery be selected from trade catalogues to meet the specifications. When the battery has been thus chosen, the dimensions and weights of individual cells can be obtained from the trade catalogues. In order to determine the total installed dimensions and weights, it will be necessary to make a layout according to standard practice. The distances between adjacent cells and the dimensions of aisles are given below in the section on *Installation*.

SPECIFICATIONS, CONTRACTS AND PROPOSALS. — (*See also article on Specifications.*) In preparing specifications for a storage-battery plant and accessories, special care should be taken to avoid drawing up specifications in such a manner as needlessly to embarrass the manufacturers who are requested to bid.

Preliminary Specifications. — It is recommended that preliminary specifications of a very general nature be prepared. These specifications should contain complete detailed data of the conditions to be met, so that the manufacturers who are requested to bid can readily determine the number and capacity of cells, the proper scheme of operation, the correct design of booster, switchboard and other accessories recommended by them to meet the requirements in hand. That is, the preliminary specifications should state plainly just what the battery is intended to accomplish. These preliminary specifications should be sent to the manufacturer with a request for a complete proposal.

Manufacturer's Proposal. — This proposal should give detail specifications covering the apparatus recommended by the manufacturer. In order to obtain the best results, it is recommended that after these proposals are received, the prospective purchaser confer with the bidders that are to be considered, and that complete final specifications be prepared, covering all details of the necessary equipment. These final specifications can then be sent to the manufacturers for their final bids.

Final Specifications. — As a guide in preparing the final specifications the points enumerated below should be thoroughly covered:

Number of cells;
Number of plates in elements initially installed;
Size of plates;
Capacity of the elements initially installed;
Charging rate of the elements initially installed;
Size of the containing vessels expressed in the number of plates which the vessel can contain;
Separators and supports;
Electrolyte;
Insulation;
Assembling and lead burning;
Bus bars, both plain and reënforced;
End-cell switches;
All copper work and cables;
Switchboard in detail;
Detailed specifications for booster and exciter apparatus according to the A.I.E.E. Standardization Rules.
Foundation for booster and switchboard;
Testing instruments;
Battery room;
Erection;
Skilled and unskilled labor;
First charge;
Operation;
Test;
Freight, cartage;
Delivery;
General scheme of operation;
Temporary work;
Cutting of walls, etc.;
Access, storage and hoisting;
Acceptance.

If specifications are drawn, covering all of these points clearly and if the specifications are attached to, and form part of, the contract, no trouble should arise in the future from misunderstandings.

Contract. —The contract should cover the price, time of payments, guarantee, protection from patent litigation and insurance of the material during construction.

INSTALLATION AND ERECTION. — *Never install any battery without following explicitly the detailed instructions furnished by the manufacturer who made the battery.*

If the battery is of considerable capacity, detail drawings showing the method of installation should be obtained from the battery manufacturer. The leading manufacturers issue printed instructions and detail drawings describing the method of installation. Much time and money can be saved by obtaining these data from the battery manufacturers.

Spacing of Glass Jars. —The spacing between cells along rows varies from 1½ inches with the smaller types of multiple plate-glass cell batteries to 3½ inches for the largest size multiple plate-glass cell batteries. This space is the space from jar to jar. It is standard practice to place the jars on wood or glass sand trays filled with sand; the distance between the sand trays along the rows varies from ½ inch to 2⅛ inches, depending upon the size of the glass jars. As the outside dimensions of the sand trays are not usually given in trade catalogues, it would be well in figuring the length of the rows to use the spacing between glass jars as given above, for the outside dimensions of the glass jars are usually stated.

With glass-jar batteries the aisle space between the rows should never be less than 24 inches, and aisles of 36 inches are recommended. In the case of double rows or where a row is installed near a wall or partition, the distance between rows, or the distance between a row and the wall, should not be less than 6 inches.

All batteries should be installed in one tier, if space is available, though glass-

in two or three tiers, if more space is not available. In installing batteries in more than one tier, sufficient headroom should be allowed in each tier to permit the removal of the elements from the jars without displacing the jars. The minimum headroom for a single-tier glass-jar battery varies from 4½ feet to 5 feet; for two tiers from 5 feet to 7½ feet and for three tiers from 7 feet to 12 feet, depending upon the size of the battery. In all cases the ceiling of the battery room should be of sufficient height to allow for the passage of a man without stooping.

Spacing of Lead-lined Tanks. — Lead-lined tank batteries should always be installed in one tier, if space is available. More than one tier should not be installed without consulting with the battery manufacturer. With lead-lined tanks the distance between tanks along rows is from 2 to 2¼ inches. The aisle space between rows should never be less than 30 inches and should always be sufficient to allow the tank to be pulled out into the aisle for repairs. Where space will not allow the tank to be pulled out its full length the aisle should have at least sufficient width to allow the tank to be stood on end in the aisle. In double rows or in rows next to the wall, at least 18 inches should be allowed between rows or between the tanks and the walls so that a man can get in for examination. The battery room should have sufficient headroom for a man to walk upright. With large-sized batteries where the amount of gases liberated on overcharge is considerable, sufficient headroom should be allowed for proper ventilation.

Dimensions of Containers. — For any given type of plate, either in glass jars or lead-lined wood tanks, there is one dimension for all jars or tanks which is practically constant, independent of the number of plates in the cell. This is the dimension parallel to the horizontal edge of the plates. This dimension is usually specified in trade catalogues as the "width." The other dimension is the dimension across the row and is usually specified in trade catalogues as the "length."

Dimensions of Battery Room. — Keeping in mind these definitions one can determine from trade catalogues the approximate inside dimensions of a battery room necessary to house the battery in question. Note, however, that any manufacturer will gladly furnish a sketch showing an ideal layout for a given battery and such a layout should always be obtained from the manufacturer, if there is sufficient time. If there is available space in a building already built, the battery manufacturer will gladly prepare a sketch showing the layout of any given battery in the available space.

Insulation of Cells. — Cells in stationary batteries, whether in glass jars or in wood tanks, must be insulated from the ground and from each other.

Glass jars are usually mounted in glass or wooden sand trays which rest on glass insulators. The glass insulators, in turn, rest on wooden racks or stringers, these racks or stringers being mounted on vitrified brick set on the battery room floor.

For lead-lined wood-tank cells the standard practice at present is to mount each tank on a sufficient number of oil insulators. These insulators consist of a glass insulator provided with a circular trough partly filled with oil, this oil surrounding a central section which supports the tank. Over the insulator is placed a lead-alloy cap, designed to exclude spray or other foreign matter from the oil. This cap rests on the central section of the glass insulator, there being no connection between the tank and the glass except at this section. The oil around this central section of glass is for the purpose of preventing a film of acid from collecting thereon; if, by any chance, acid or water should get into the trough, it would sink to the bottom, the oil would float on top, and perfect insulation would be maintained.

The glass insulator rests upon a heavy earthenware truncated cone, having three feet. Between this cone and the glass is a Y-shaped lead washer. Thus three-point support is obtained between the floor and the earthenware, and between the earthenware and the glass. This form of support is not necessary between the glass and the tank, because the wood and lead cap take up any surface inequalities.

Connections between Cells. — In glass-jar batteries of small size, elements in adjacent cells are usually bolted together. In the larger-sized glass-jar batteries and in all lead-lined wood-tank batteries the positive plates in one cell are burned to the negative plates in the adjacent cell through the medium of a lead bus bar. The bus bars at the ends of rows, and wherever current taps are made, are reënforced by a bar of copper embedded in the lead.

Battery-room Design. — Though no battery should be installed without specific instructions from the manufacturer, the following points should receive special attention.

Floor. — The floor of the battery room should be made acidproof and should be graded to drain. A wood floor should never be used, as it is bound to become acid soaked and eventually be destroyed. For small batteries a cement floor can be used, but, unless it is kept thoroughly washed, acid will eat holes in it. A glazed tile floor is preferable.

Ventilation. — All battery rooms should be well ventilated. With small batteries natural ventilation is usually sufficient; with large-capacity batteries, where the gassing during overcharge is considerable, artificial ventilation should be provided. Exhaust ventilation is preferable to compression ventilation.

Temperature. — The temperature of the battery room should be kept as near 70° F. as possible.

Exposed Metal. — The amount of exposed iron or metal work in the battery room should be reduced to a minimum on account of the action of acid fumes upon it. Any iron or metal work that must be in the battery room should be protected with an acid-resisting paint.

OPERATION. — *Never operate any battery in any manner except in accordance with the instructions of the battery manufacturer furnishing the battery.*

With all large battery plants there should be supplied by the manufacturer the proper testing instruments and detail instructions for the operation of the battery under the conditions obtaining. The blank forms furnished by the manufacturer should be filled in at regular intervals and mailed to the manufacturer for analysis and recommendations.

No general instructions for the proper operation of a battery are given in this article, since the different manufacturers differ in their opinions on certain points of operation.

Printed instructions for operating any type of battery can be obtained free of charge from the manufacturer.

Attention from Operator. — The successful operation of a battery plant does not require much time from the operator, but attention given the battery should be systematic and absolutely in accordance with the instructions furnished by the manufacturer. If the manufacturer's instructions are followed implicitly and systematically, it will be found that the battery can be kept in good condition with a small amount of labor and time. If the operator neglects to follow the regular instructions and does not appeal to the manufacturer until he gets into trouble, the usual result will be considerable loss in time and money.

Addition of Water. — Pure distilled water, or natural water that has been analyzed and approved by the battery manufacturer, should be added to the

of pure, natural water, and if distilled water cannot be purchased cheaply, a distilling outfit will usually be found necessary with large sizes of batteries. Standard water stills, for this purpose, can be purchased on the market.

Addition of Acid. — *Acid should never be added to a battery except upon the recommendation of the battery manufacturer.* The manufacturer should specify the specific gravity and the proper amount of acid.

REPAIRS. — Very few repairs, other than battery plates, should be required. For replacing the plates in the larger sizes of batteries, a lead-burning outfit and the necessary lead-burning material will usually be required. No one but a skilled lead burner should attempt to burn in plates.

Smaller sizes of batteries, with bolted connections between adjacent cells, can be purchased from the manufacturer with each element assembled.

Leaky Tanks. — A leaky tank should be repaired immediately. No one but an expert sheet-lead burner should be allowed to repair a leaky lead-lined tank. To repair the leaky lead-lined tank it will be necessary to cut loose from the bus bars all of the plates in the leaky tank and remove the tank into the aisle. If it is necessary to keep the rest of the battery in commission while the repairs are being made, the cell or cells cut out should be jumped by a jumper of sufficient current-carrying capacity.

FIRST COST. — It is impossible to give exact figures for the total cost of installation of a complete battery plant of any size. An analysis of the first costs of a great many plants now in operation shows that the first cost per kilowatt for the entire battery installation, exclusive of building, varies from $75.00 per kilowatt to $250.00 per kilowatt. The kilowatt rating as used here and elsewhere in this article is an arbitrary rating determined by multiplying the one-hour discharge rate in amperes (four times the normal rate) by double the number of cells.

ANNUAL COST. — The total annual cost includes operation, maintenance, depreciation and interest.

Operating Cost. — The operating cost will consist largely of labor. All material except necessary water should be included under maintenance.

Maintenance and Depreciation. — The cost of maintenance of a battery varies with the conditions. Other things being equal, the life of a battery is dependent upon the work done. The maintenance cost of a battery varies from 4 per cent to 10 per cent per annum. When the battery is used only for strictly emergency service the maintenance cost may be less than 4 per cent.

These figures cover not only maintenance, but also what is commonly included under the term depreciation. The plate being the essential component of the battery, plate renewals, which are made from time to time, involve all improvements that have been made in design and construction and serve to bring the battery up to date. An increase of voltage or capacity to meet changed conditions may be effected by the addition of cells or by increasing the number of plates in each cell, without sacrifice of the original investment. In the opinion of the writer there is, therefore, little, if any, true depreciation in a battery installation which is properly maintained.

[TALIAFERRO MILTON.]

BEARINGS. — (*See also Friction; Lubricants and Lubrication; Shafting.*) The common types of shaft bearings may be classified as follows:

Plain Cylindrical Bearings. — The usual form of bearing is a metal cylinder of cast iron, brass, bronze or gun-metal, mounted in a pedestal, bracket or frame, which serves as a support for the shaft. The portion of the shaft within the bearing is called the journal. Plain bearings are usually lined with some soft metal, such as babbitt metal or other white metal. In a self-aligning bearing the seating of the bearing in the pedestal is made a portion of a sphere, so that the bush may automatically align itself with the shaft. Cylindrical bearings are sometimes provided with an oil bath within the pedestal just below the bearing proper; rings or chains running loosely over the journal through slots in the bearing and dipping into this bath supply a steady stream of oil to the rubbing surfaces.

Roller Bearings. — In this type of bearing the journal is supported on rollers which are in turn supported by smaller shafts in smaller bearings. The rollers support the journal of the main shaft.

Step Bearing. — A step bearing is essentially a large pivot bearing used at the end of vertical shafts carrying a heavy load. The end of the shaft is provided with a steel plate or "step," which rests on a second plate or bearing. The bearing proper may be either of the ball or roller type, or may be a plane surface with one or more grooves into which oil can be forced under pressure. For heavy loads on a plain step bearing the pressure of the oil must be sufficient to actually raise the step by a small amount so that a thin film of oil is formed between the step and the bearing.

Thrust Bearings. — Thrust bearings are used on horizontal shafts when the shaft is subjected to a horizontal thrust. They are similar to step bearings for vertical shafts, except that a collar fitting around the shaft is used instead of a plate at the end of the shaft. Steamship shaft bearings have numerous collars on the shaft, with thrust blocks between them. Roller or ball bearings may be used instead of collars.

Ball Bearings. — A ball bearing consists essentially of a track of curved cross section which is filled with a set of balls.

Pivot Bearings. — Various types of pivot bearings are used. The pivot may be either a flat surface, a pointed cone, a truncated cone, a hemisphere or a surface of special form, such as Shiele's "tractrix."

ALLOWABLE LOADS AND SPEEDS. — If the pressure on a bearing is too great the oil film between journal and bearing surface will be destroyed and the bearing will overheat and "seize." Various formulas have been developed for the allowable pressure in terms of the speed and type of bearing.

Safe Loads, Line Shaft and Mill Bearings. — F. W. Taylor (*Trans. A.S.M.E., 1905*), as the result of an investigation of line shaft and mill bearings that were running near the limit of durability and heating, yet not dangerously heating, gives the formula

$$p = \frac{400}{v},$$

where p = pressure in pounds per square inch of projected area (i.e., product of diameter of the journal by its length) and v = peripheral velocity of journal in feet per second.

The formula is applicable to bearings in ordinary shop or mill use on shafting which is intended to run with the care and attention which such bearings usually receive, and gives the maximum or most severe duty to which it is safe to subject

ordinary *chain* or *oiled* ball- and socket-bearings which are *babbitted*. It is not safe for ordinary shafting to use *cast-iron boxes*, with either sight feed, wick feed or grease-cup oiling, under as severe conditions as $p \times v = 200$.

Safe Loads, Miscellaneous Plain Bearings. — Archbutt and Deeley's *Lubrication and Lubricants* gives the following table of allowable pressures in pounds per square inch of projected area of different bearings:

Crank pin of shearing and punching machine, hard steel, intermittent load bearing	3000
Bronze crosshead neck journals	1200
Crank pins, large slow engine	800–900
Crank pins, marine engines	400–500
Main crankshaft bearing, fast marine	400
Same, slow marine	600
Railway coach journals	300–400
Flywheel shaft journals	150–200
Small engine crank pin	150–200
Small slide block, marine engine	100
Stationary engine slide blocks	25–125
Same, usual case	30– 60
Propeller thrust bearings	50– 70
Shafts in cast-iron steps, high speed	15

Safe Loads, Roller Bearings. — The following table gives the safe load in pounds for Mossberg roller bearings (*Trans. A.S.M.E., 1905*). D = diameter of journal, in inches; d = diameter of roll, in inches; N = number of rolls; P = safe load on journals, in pounds. The rolls are enclosed in a bronze supporting cage.

D	d	N	P	D	d	N	P	D	d	N	P
2	1/4	20	3,500	6	11/16	24	50,000	15	1 3/8	28	255,000
2 1/2	5/16	22	7,000	7	13/16	22	70,000	18	1 3/8	32	325,000
3	3/8	22	13,000	8	7/8	22	90,000	20	1 1/2	34	400,000
4	7/16	24	24,000	9	1	24	115,000	24	1 1/2	38	576,000
5	9/16	24	37,000	12	1 1/4	26	175,000	..	...	..	......

Surface speed of journal from 0 to 50 feet per minute. Length of journal 1 1/2 diameters. The rolls are made of tool steel not too high in carbon, and of spring temper. The journal or shaft should be made not above a medium spring temper. The box should be made of high-carbon steel and tempered as hard as possible.

Safe Loads, Ball Bearings. — The following formula is given by Mr. Henry Hess, 1910. See also paper by Mr. Hess in *Trans. A.S.M.E., 1907*.

Let

W = total safe load on bearing in pounds,
n = number of balls,
d = diameter of balls in *eighths of an inch*.

Then for *radial* (cylindrical) bearings

$$W = Knd^2,$$

where K ranges from 0.9 to 9 depending upon the condition and type of bearing and the hardness of the balls, but for ordinary speeds is practically independent of the speed. (*See Kent's Mechanical Engineers' Pocket-Book.*)

For *thrust* bearings

$$W = \frac{K_1 n d^2}{\sqrt[3]{N}},$$

where N is the number of revolutions per minute, which may range from 3000 down to 1 revolution per minute, as for crane hooks and similar elements. For high quality ball K_1 ranges from 25 to 40 for a race having a cross section of radius $1.66 \times$ (radius of balls). For unhardened steel, occasionally used for very large races, $K_1 = 0.5$.

In both types of bearings the balls must be carefully selected to make sure that all that are used in the same bearing do not vary among one another by more than 0.0001 inch. A ball that is more than that larger than its fellows will sustain more than its proportion of the load, and may therefore be overloaded and will in turn overload the races.

FRICTION OF BEARINGS. — The coefficient of friction of a well-lubricated plain cylindrical bearing is practically independent of the projected area of the journal, the pressure per unit area remaining constant, and in the case of plain bearings is also practically independent of the nature of the rubbing surfaces, provided these are smooth.

Friction of Plain Bearings. — The coefficient of friction of plain bearings however, does depend to a very great extent upon the following factors:

1. The method of lubrication.
2. The nature of the lubricant.
3. The temperature of the lubricant.
4. The peripheral velocity of the journal.
5. The pressure of the journal on the bearing surface.

1. The more perfectly the bearing is bathed in oil the less will be the coefficient of friction. The friction coefficient of a scantily lubricated bearing may be from 6 to 10 times the coefficient when an oil bath is used.

2. As a rule the lower the viscosity of an oil the less will be the coefficient of friction. There are other factors, however, which must be taken into account in selecting the proper lubricant for any service (*see article on Lubricants and Lubrication*).

3, 4 and 5. The variation of the friction coefficient with temperature, speed and pressure is shown by the curves in Fig. 1. The pressures are nominal

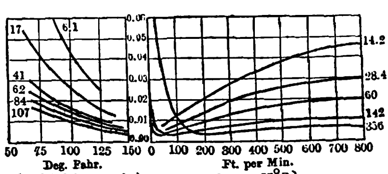

Fig. 1. Numbers at end of curves are pressures in lb. per sq. in.

pressures, i.e., pounds per square inch of projected area of journal. These curves are taken from a paper by Stribeck (*Zeit. Ver. Deutsch. Ing., 1902, Vol. 46, p. 1341*), and are test results on a Sellers bearing with oil rings; journal 13 inches long, 2.75 inches in diameter, lubricated with "gas motor oil." These curves are typical of ordinary bearings.

POWER LOST IN BEARINGS. — Let

f = coefficient of friction,
W = weight on journal or pivot in pounds,
r = radius in inches,
d = diameter in inches,
S = space in feet through which sliding takes place per minute.
r_1 = inner radius in inches,
r_2 = outer radius in inches,
n = number of revolutions per minute,
a = the half-angle of the cone, i.e., the angle of the slope with the axis.

Type of bearing	Friction torque in in.-lb.	Power loss ft.-lb. per min.
Flat surfaces	....	fWS
Shafts and journals	$\frac{1}{2}\ fWd$	$0.2618 fW\ dn$
Flat pivots	$\frac{2}{3} fWr$	$0.349 fWrn$
Collar-bearing	$\frac{2}{3} fW \frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$	$0.349 fWn \frac{r_2^3 - r_1^3}{r_2^2 - r_1^2}$
Conical pivot	$\frac{2}{3} fWr \operatorname{cosec} a$	$0.349 fWrn \operatorname{cosec} a$
Conical journal	$\frac{2}{3} fWr \sec a$	$0.349 fWrn \sec a$
Truncated-cone pivot	$\frac{2}{3} fW \frac{r_2^3 - r_1^3}{r_2 \sin a}$	$0.349 fWn \frac{r_2^3 - r_1^3}{r_2 \sin a}$
Hemispherical pivot	fWr	$0.5236 fWrn$
Tractrix, or Schiele's "anti-friction" pivot	fWr	$0.5236 fWrn$

It should be noted that for peripheral speeds of 100 feet and over the coefficient of friction is approximately proportional to the square root of the peripheral velocity of the journal. These particular curves also indicate that the coefficient of friction is approximately inversely proportional to the square root of the pressure. Other experimenters, however, have found that this variation is inversely as the first power of the pressure.

Friction of Roller and Ball Bearings. — The friction coefficient of a well-made annular ball bearing is 0.001 and 0.002 of the total load on the journal and is independent of the speed and load. The friction coefficient of a good roller bearing under normal loads and speed is from 0.0035 to 0.014; it rises very much if the load is light. It increases also when the speeds are very low, though not so much as with plain bearings. (*Henry Hess.*)

Lubrication is absolutely necessary with ball-and-roller bearings, although the contrary claim is often advanced. Under favorable conditions an almost imperceptible film is sufficient; a sufficient quantity to immerse half the lowest ball should always be provided as a rust preventive. Rust and grit must be kept out of ball-and-roller bearings. Acid or rancid lubricants are as destructive as rust. (*Henry Hess.*)

[Wm. Kent.]

BELTS AND BELTING. — (*See also Ropes and Rope Drive.*) Belts are usually made of tanned leather, though rubber belts are frequently employed, as well as various woven fabrics. Rubber belts are made of two or more layers of canvas connected together with a rubber composition, and then heated until the rubber vulcanizes. The "ply" of a rubber belt is the number of layers of canvas. Leather belts are referred to as single, light-double, medium-double, standard-double and 3-ply.

Thickness of Belts. — The following figures are from a paper by Samuel Webber (*Am. Mach., May 11, 1909*). The thickness of leather belts, however, is variable, depending on the hide and process of manufacture.

BELT THICKNESS, INCHES

Leather		Rubber, 30-oz. duck, new rubber vulcanized	
Single thickness	1/6	3-ply	0.18
Light-double	1/4	4-ply	0.24
Medium-double	5/16	5-ply	0.30
Standard-double	1/8	6-ply	0.35
3-ply	9/16	7-ply	0.40
		8-ply	0.45

Weight. — The average weight of leather per cubic inch is 1/30 pound (*Barth*). The average weight of rubber belting made of 30-ounce duck is about 0.045 pound per cubic inch.

Strength. — The strength of the solid leather in belts is from 2000 to 5000 pounds per square inch; at the lacings, even if well put together, only from 1000 to 1500. If riveted, the joint should have half the strength of the solid belt. Rubber belts have approximately the same tensile strength as leather belts. The working tension on the driving side is generally taken at not over one-third of the strength of the lacing, or from one-eighth to one-sixteenth of the strength of the solid belt.

Belt Tension. — Let

T_1 = actual, or "total," tension in pounds per square inch on driving side of belt,
T_2 = actual tension in pounds per square inch on slack side of belt,
T_0 = "initial" tension in belt, i.e., the tension in each side when the belt is at rest,
$T = T_1 - T_2$ = effective tension in pounds per square inch, i.e., T corresponds to the force actually driving the driven pulley,
T_c = the tension produced in the belt due to centrifugal action as it goes around the pulleys,
m = weight of belt per cubic inch in pounds,
f = coefficient of friction between belt and pulley,

n = ratio of arc of contact between belt and pulley to an arc of 180°, i.e., if the arc of contact is 180°, $n = 1$,

$C = 1 - \epsilon^{-nf\pi}$. The value of $\epsilon^{-nf\pi}$ may be found directly from the table in the article on *Exponential Functions*, putting $nf\pi = x$,

V = velocity of belt in feet per minute.

Then

$$T_c = \frac{mV^2}{9660}, \qquad (1)$$

$$T = C(T_1 - T_c), \qquad (2)$$

$$T_2 = T_1 - C(T_1 - T_c), \qquad (3)$$

$$T_0 = \left(\frac{\sqrt{T_1} + \sqrt{T_2}}{2}\right)^2 \text{ approximately.*} \qquad (4)$$

Barth recommends that for belts running at various speeds the initial tension T_0 should not be the same in all belts, but that the belts should be tightened initially to such a tension that under load the sum

$$A = T_1 + \tfrac{1}{2} T_2 \qquad (5)$$

is a constant. Barth also states, basing his conclusion in part on the studies of the economics of belting made by F. W. Taylor (*Trans. A.S.M.E., Vol. 15, p. 204*), that the best values of A for greatest economy are the following:

	Machine belts	Counter-shaft belts
Maximum value of A, belt first put on	320	240
Minimum value of A, belt to be retightened	240	160

These values of A are for full-load conditions. The corresponding values of the various tensions are given below.

Belt Friction and Belt Slip. — The value of the factor C depends upon the coefficient of belt friction, which is subject to considerable variation, depending upon the condition of the belt and pulleys. Barth gives the following formula for f for leather belts on cast-iron pulleys

$$f = 0.54 - \frac{140}{500 + V}.$$

Barth also gives a formula for the belt slip which may be written

$$s = \frac{V_1 - V_2}{V} = \frac{320}{V}\left(\frac{1 + 0.0055\,V}{85 + 0.03\,V}\right),$$

where V_1 and V_2 are the peripheral velocities of the driving and driven pulleys respectively.

* See paper by C. G. Barth, *Trans. A.S.M.E.*, 1909, Vol. 31, p. 29. In this paper Barth also gives a more exact formula, and takes into consideration the difference in the relation between T_1, T_2 and T_0 for vertical and horizontal belts.

Power Loss Due to Belt Slip is proportional to the slip, i.e., if the slip is 0.03 the power lost is 3 per cent of the power transmitted by the belt. Under normal conditions the power loss due to belt slip is from 2 to 4 per cent. The power loss in mill shafting due to the friction of the shaft bearings ranges from 10 to 60 per cent, depending upon the type of bearing, belt tension, etc., See article on *Bearings*.

Power Transmitted by Belt. — Let

V = velocity of belt in feet per minute,
w = width of belt, in inches,
t = thickness of belt, in inches,
m = weight, in pounds, of 1 cubic inch of belt,
T_1 = actual tension in driving side of belt in pounds per square inch of belt cross-section,
s = slip of belt as a fraction of belt speed.

Then the horse-power transmitted by the belt is

$$P = \frac{wtCVT_1}{33{,}000}\left(1 - \frac{mV^2}{9660\,T_1}\right),$$

where C, defined above, depends on the belt friction and arc of contact between belt and pulley.

As a rough approximation C may be taken equal to 0.6, and the second term in the bracket zero, at least for low speeds, and the formula then becomes

$$P = \frac{wtVT_1}{55{,}000},$$

or the horse-power transmitted per square inch of belt cross-section is

$$p = \frac{VT_1}{55{,}000}.$$

The power lost in the transmission from one pulley to the other, excluding the loss due to shaft friction, is sP, the driving pulley absorbing approximately $(P + 0.5\,sP)$ horse-power and the driven pulley receiving $(P - 0.5\,sP)$ horse-power.

The following tables are derived from curves in the paper by Barth above referred to.

HORSE-POWER TRANSMITTED BY BELTS DRIVING MACHINES
(For $A = T_1 + 0.5\,T_2 = 240$)

Velocity, ft. per min.	500	1000	2000	3000	4000	5000	6000
Initial tension, T_0	124	120	121	128	136	144	152
Centrifugal tension T_c	0+	3	13	31	56	86	124
Difference, $T_0 - T_c$.........	123	117	108	97	80	58	28
Tension on tight side, T_1...	210	212	211	207	198	187	173
Tension on slack side, T_2...	60	54	57	68	84	107	134
Effective pull, $T_1 - T_2$	150	158	154	139	114	80	39
Sum of tensions $T_1 + T_2$	270	268	269	274	282	294	307
H.p. per sq. in. of section..	2.27	4.79	9.33	12.64	13.82	12.12	7.09

HORSE-POWER TRANSMITTED BY BELTS DRIVING COUNTER-SHAFTS

(For $A=T_1+0.5\ T_2=160$.)

Velocity of belt, ft. per min.	500	1000	2000	3000	4000	5000
Initial tension, T_0	82	81	83	89	96	102
Tension on tight side, T_1	140	141	140	134	125	114
Tension on slack side, T_2	40	38	41	53	69	92
Effective pull, T_1-T_2	100	103	99	81	56	22
Sum of tensions	180	179	181	187	194	206
H.p. per sq. in. of section	1.51	3.12	6.04	7.36	6.79	3.33

Proper Size of Belt to Transmit a Given Amount of Power. — Using the same notation as in the preceding paragraph, the proper cross-section of the belt in square inches is approximately

$$wt = \frac{55{,}000\ P}{VT_1},$$

or exactly

$$wt = \frac{33{,}000\ P}{CVT_1\left(1 - \frac{mV^2}{9660\ T_1}\right)}.$$

The various "handy formulas" for determining the proper cross-section of belt are all of the form of the approximate formula, and differ only in regard to the proper value to assign to the tension T_1. A working tension, that is the difference between the tensions on the tight and slack sides of the belt, of 45 pounds for a single (thickness) belt 1 inch wide is commonly used, giving a nominal tension of $6 \times 45 = 270$ pounds per square inch. Taking the coefficient C at 0.6, the actual tension in a belt designed in accordance with this rule is 450 pounds per square inch. The value of C varies through a wide range, say from 0.25 to 0.90, chiefly due to the variability of the coefficient of friction.

The following table, deduced from Barth's curves, may be considered as representative of modern practice.

CROSS-SECTION OF LEATHER BELT PER HORSE-POWER TRANSMITTED, IN SQUARE INCHES

Speed, ft. per min.	500	1000	2000	3000	4000	5000	6000
Machine belts	0.44	0.209	0.107	0.079	0.072	0.082	0.141
Countershaft belts	0.662	0.320	0.166	0.136	0.147	0.300	.....

All belts should have a contact area with the smaller pulley of at least 165 degrees. If this is not possible to obtain under normal conditions an idler should be provided to increase the belt contact.

Pulley Face and Belt Speed.* — The following table may be used for determining the pulley face and best belt speed for moderate-speed machines. For slow-speed machines the pulley sizes are the same as those used with moderate machines of the same frame dimensions.

PULLEY FACE AND BELT SPEED

Horse-power	Kilowatts	Belt width in inches	Pulley face in inches	Belt speed in feet per minute for moderate-speed machines
1 to under 5	1 to under 4	2	2½	2000
5 " 10	4 " 8	3	3½	2500
10 " 15	8 " 11	4	4½	2500
15 " 20	11 " 15	5	6	2500
20 " 25	15 " 19	6	7	3000
25 " 30	19 " 23	7	8	3000
30 " 40	23 " 30	8	9	3000
40 " 50	30 " 37	10	11	3000
50 " 60	37 " 45	12	13	3000
60 " 75	45 " 56	14	15	3000
75 " 100	56 " 75	16	17	3500
100 " 125	75 " 93	16	17	4000
125 " 150	93 " 112	18	19	4000
150 " 200	112 " 159	20	21	4500

950 " 1050	709 " 783	60	62	5000

Relations of Driving and Driven Pulleys.* — The maximum ratio between the diameters of the driving and driven pulleys should not exceed 6 : 1. The ratio will determine the distance between the pulley centers, and good proportions are given in the accompanying table.

CARE AND OPERATION OF BELTS. — The following is taken from an article by F. W. Taylor (*Trans. A.S.M.E., Vol. 15, p. 204*).

The best distance from center to center of shafts is from 20 to 25 feet.

Idler pulleys work most satisfactorily when located on the slack side of the belt about one-quarter way from the driving pulley.

Belts are more durable and work more satisfactorily made narrow and thick, rather than wide and thin.

It is safe and advisable to use a double belt on a pulley 12 inches diameter or larger; a triple belt on a pulley 20 inches diameter or larger; a quadruple belt on a pulley 30 inches diameter or larger.

As belts increase in width they should also be made thicker.

Approximate Ratio	Minimum Distance Between Centers in Feet
2 : 1	8
3 : 1	10
4 : 1	12
5 : 1	15
6 : 1	20

The ends of the belt should be fastened together by splicing and cementing instead of lacing, wiring or using hooks or clamps of any kind.

Belts should be cleaned and greased every five to six months.

Belt-clamps having spring-balances between the two pairs of clamps should be used for weighing the tension of the belt accurately each time it is tightened.

Double leather belts, when treated with great care and run night and day at moderate speed, should last for 18 years (the tension being adjusted in accordance with Barth's rules).

In figuring the total expense of belting, and the manufacturing cost chargeable to this account, by far the largest item is the time lost on the machines while belts are being relaced and repaired.

The total stretch of leather belting exceeds 6 per cent of the original length.

The stretch during the first six months of the life of belts is 15 per cent of their entire stretch (the tension being adjusted in accordance with Barth's rules).

A double belt will stretch 0.81 per cent of its length before requiring to be tightened (the tension being adjusted in accordance with Barth's rules).

The most important consideration in making up tables and rules for the use and care of belting is how to secure the minimum of interruptions to manufacture from this source.

The average double belt when running night and day in a machine shop will cause an interruption to manufacture not oftener than once in sixteen months (the tension being adjusted in accordance with Barth's rules).

The oak-tanned and fulled belts showed themselves to be superior in all respects except the coefficient of friction to either the oak-tanned not fulled, the semi-rawhide, or rawhide with tanned face.

Belts of any width can be successfully shifted backward and forward on tight and loose pulleys. Belts running between 5000 and 6000 feet per minute and driving 300 h.p. are now being daily shifted on tight and loose pulleys to throw lines of shafting in and out of use.

The best form of belt-shifter for wide belts is a pair of rollers twice the width of belt, either of which can be pressed onto the flat surface of the belt on its slack side close to the driven pulley, the axis of the roller making an angle of 75° with the center line of the belt.

Dressings for Leather Belts. — We advise that no belt dressing should be used except when the belt becomes dry and husky, and in such instances we recommend the use of a dressing. Where this is not used beef tallow at blood-warm temperature should be applied and then dried either by artificial heat

or the sun. The addition of beeswax to the tallow will be of some service if the belts are used in wet or damp places. Our experience convinces us that resin should never be used on leather belting. (*Fayerweather and Ladew.*)

Some forms of belt dressing, the compositions of which have not been published, appear to have the property of increasing the coefficient of friction between the belt and the pulley, enabling a given power to be transmitted with a lower belt tension than with undressed belts. C. W. Evans (*Power, Dec., 1905*) gives a diagram, plotted from tests, which shows that three of these compositions gave increased transmission for a given tension, ranging from about 10 per cent for 90 pounds tension per inch of width to 100 per cent increase with 20 pounds tension.

Dressings for Rubber Belts. — Rubber belts will be improved, and their durability increased, by putting on with a painter's brush, and letting it dry, a composition made of equal parts of red lead, black lead, French yellow and litharge, mixed with boiled linseed oil and japan enough to make it dry quickly. The effect of this will be to produce a finely polished surface. If, from dust or other cause, the belt should slip, it should be lightly moistened on the side next the pulley with boiled linseed oil. (*From circulars of manufacturers.*)

Lacing of Belts. — In punching a belt for lacing, use an oval punch, the longer diameter of the punch being parallel with the sides of the belt. Punch two rows of holes in each end, placed zigzag. In a 3-inch belt there should be four holes in each end — two in each row. In a 6-inch belt, seven holes — four in the row nearest the end. A 10-inch belt should have nine holes. The edge of the holes should not come nearer than ¾ inch from the sides, nor ⅞ inch from the ends of the belt. The second row should be at least 1¾ inches from the end. On wide belts these distances should be even a little greater.

Begin to lace in the center of the belt and take care to keep the ends exactly in line, and to lace both sides with equal tightness. The lacing should not be crossed on the side of the belt that runs next the pulley. In taking up belts observe the same rules as in putting on new ones.

Setting a Belt on Quarter-twist. — A belt must run squarely on to the pulley. To connect with a belt two horizontal shafts at right angles with each other, say an engine-shaft near the floor with a line attached to the ceiling, will require a quarter-turn. First, ascertain the central point on the face of each pulley at the extremity of the horizontal diameter where the belt will leave the pulley, and then set that point on the driven pulley plumb over the corresponding point on the driver. This will cause the belt to run squarely on to each pulley, and it will leave at an angle greater or less, according to the size of the pulleys and their distance from each other.

In quarter-twist belts, in order that the belt may remain on the pulleys, the central plane on each pulley must pass through the point of delivery of the other pulley. This arrangement does not admit of reversed motion.

[Wm. Kent.]

BLOCKS AND TACKLE. — (*See also Ropes and Rope Drive; Chains and Chain Drive.*) A simple block used with rope tackle consists of one or more pulleys mounted in a casing or shell. They may be single, double, triple, etc., depending upon the number of sheaves or pulleys. In chain blocks, instead of simple pulleys, spur or worm and wheel gearing (*see Gears and Gearing*) or differential pulleys are used. In the triplex block, made by the Yale and Towne Co., the power is transmitted to the hoisting-chain wheel by means of a train of spur gearing operated by the hand chain. In the duplex block the power is transmitted through a worm wheel and screw.

Fig. 1 shows schematically a differential pulley. The two upper pulleys are rigidly fastened together and rotate as one piece. The rims of these pulleys are shaped to mesh with the links of the chain and prevent the latter from slipping. Let D_1 and D_2 be the respective diameters of the larger and smaller upper pulleys. Then if the diameter of the lower pulley is $(D_1 + D_2)/2$, the pull P' required to raise a load W, neglecting friction, is

$$P' = \frac{D_1 - D_2}{2D_1} \cdot W.$$

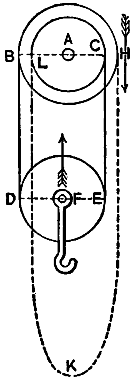

Fig. 1.

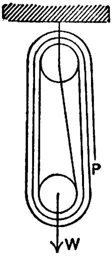

Fig. 2.

ACTUAL PULL REQUIRED; EFFICIENCY OF BLOCK AND TACKLE. — In the case of a simple block and tackle the pull P' required to raise a load W is, neglecting friction,

$$P' = \frac{W}{N},$$

where N is the number of lengths of rope shortened when the lower block rises (in Fig. 2 $N = 6$). The actual pull required is this theoretical pull P' divided by the efficiency expressed as a fraction, or

$$P = \frac{100\,W}{Ne},$$

where e = the per cent efficiency. The distance in feet through which the pulling rope must be pulled to raise the load 1 foot is equal to the number (N) of lengths of rope shortened.

In the case of a differential pulley the actual pull is

$$P = \frac{100\,(D_1 - D_2)\,W}{2D_1e},$$

where e is the per cent efficiency and the other symbols as above. The distance through which the hand chain must be pulled to raise the load 1 foot is

$$\frac{2D_1}{D_1 - D_2}.$$

In any case, if the rope or chain pulls on the lower block at an angle, the block will be pulled out of the line drawn between the load and the upper block, and the effective pull will be less than the actual pull on the rope in the ratio of the cosine of the angle the pulling rope makes with the vertical, or line of action of the resistance, to unity.

Efficiency of Rope Blocks. — S. L. Wonson, *Eng. News*, June 11, 1903, gives the following:

Number of rope lengths shortened, *N*	Manila rope, 1¼ to 2 in.		¾-inch wire rope	
	Ratio of load to pull	Efficiency, per cent, *e*	Ratio of load to pull	Efficiency, per cent, *e*
2	1.91	96	....	..
3	2.64	88	2.73	91
4	3.30	83	3.47	87
5	3.84	77	4.11	82
6	4.33	72	4.70	78
7	4.72	67	5.20	74
8	5.08	64	5.68	71
9	5.37	60	6.08	68
10	....	..	6.46	65
12	....	..	7.08	59

Pull Required with Chain Blocks. — The following table is taken from a catalogue of the Yale and Towne Co., 1908.

Capacity in tons, (2000 lb.)	Pull in pounds required on hand-chain to lift full loads			Feet of hand-chain to be pulled by operator to lift load one foot high		
	Triplex	Duplex	Differential	Triplex	Duplex	Differential
¼	...	...	72	...	...	18
½	62	68	122	21	40	24
1	82	87	216	31	59	30
1½	110	94	246	35	80	36
2	120	115	308	42	93	42
3	114	132	557	69	126	38
4	124	142	...	84	155	..
5	110	145	...	126	195	..
6	130	145	...	126	252	..
8	135	160	...	168	310	..
10	140	160	...	210	390	..

For loads from 10 to 20 tons two hand-chains are provided.

SAFE LOAD. — Blocks are usually designed to carry a load as great as that of the rope or chain which fits the grooves in the sheaves (*see Ropes and Rope Drive; Chains and Chain Drive*).

[Wm. Kent.]

BLOWERS AND COMPRESSORS. — (*See also Draft, Mechanical; Fans.*) A blower is any kind of apparatus that is used for blowing or forcing air or other gas into or out of a room or other receptacle. When it is used to draw air from a room or vessel and discharge it into another vessel or into the external atmosphere it is commonly called an "exhauster." A fan is a blower in which motion is given to the air by means of thin blades or vanes (*see Fans*). A blowing engine is a large machine in which air is compressed in and discharged from a cylinder which is fitted with a reciprocating piston. When a blowing engine delivers air at high pressures, say 30 pounds per square inch and upwards, it is called an air compressor. Following is a brief description of the several kinds of blowers.

Displacement Blowers. — Into a closed tank containing air a stream of water is caused to flow, displacing the air and blowing it out through an opening provided for it. By using two tanks with suitable valves, the action may be made continuous.

Hydraulic Blowers. — A large tank is surmounted by a vertical pipe into the top of which water enters in such a way as to "entrain" or drag air along with it, which is separated from the water when it reaches the tank and is blown out through an air pipe while the water escapes through another opening. Tests of a compressor of this kind at Magog, P. Q., Canada, showed a capacity of from 967 to 1165 cubic feet of air per minute at a pressure of 53 pounds per square inch, and an efficiency of from 60 to 70 per cent. See paper by W. O. Webber, *Trans. A.S.M.E.*, Vol. 22, p. 599.

Jet Blowers. — A jet of water, compressed air, or steam flowing into a short pipe of a diameter greater than that of the jet will induce a current of air to flow through the pipe, which may thus be used as a blower or exhauster. The steam jet is in common use for blowing air into furnaces and gas producers, and is used as an exhauster to increase the draft of chimneys. It is usually very wasteful of steam, and should be used only in emergencies, when blowing machines are not available, or when the steam used to drive the jet is also used for other purposes, as for combining with the carbon of the fuel in gas producers.

Positive Rotary Blowers. — These are built like rotary pumps, with two rotating shafts, geared together so as to turn in opposite directions, each carrying an "impeller," a casting approximating a figure 8 in section; the curve of the two impellers is so shaped that they touch or nearly touch on lines parallel to the shafts during the whole period of rotation, and also nearly touch the casing which surrounds them. A blower thus built delivers a constant quantity of air at each revolution, differing in this respect from centrifugal fans which deliver a varying quantity according to the resistance the air meets at the outlet. The economical range of these blowers is between 8 ounces and 8 pounds pressure per square inch. For higher pressures then 8 pounds the blowing engine is more economical.

Blowing Engines. — A cylinder with a reciprocating piston when used for blowing air is called a blowing engine, whether it is driven by a steam engine, a water wheel or an electric motor. Blowing engines are commonly used to furnish air to blast furnaces and Bessemer converters, at pressures of from 4 to 30 pounds per square inch. They are simple in construction, but are usually large, heavy and costly relative to the quantity and pressure of air furnished by them, on account of their moderate speeds, and there is a tendency to supplant them by

High-speed Centrifugal Compressors. — These are built on the principle of steam turbines or high-pressure centrifugal pumps and are driven at very high

speeds, 1800 to 3500 r.p.m. The General Electric Co. makes a line of these compressors for pressures ranging from 1 to 3.25 pounds per square inch, and for delivering 800 to 28,000 cubic feet of free air per minute. By using several such compressors in series, one delivering into another, pressures of 100 pounds per square inch may be obtained.

POWER AND EFFICIENCY.—The useful work done by a blower is that equivalent to the isothermal compression of the air to the pressure in the receiver (or to the static plus the velocity pressure in the delivery main if the air were cooled to the atmospheric temperature) plus the work of delivering it against that pressure. If P_1 = absolute pressure at inlet in pounds per square foot; P_2 = pressure in the receiver; V_1 = volume of entering air at the pressure P_1, in cubic feet per minute, then useful work is foot-pounds per minute = $P_1V_1 \log_e \frac{P_2}{P_1}$. The useful or "air horse-power" is this quantity divided by 33,000.

When P_2 is but slightly in excess of P_1 the work per minute is P_2V_1 nearly, the error being less than 5 per cent when $P_2 = 1.1\ P_1$, and less than 1 per cent when $P_2 = 1.01\ P_1$.

When the air is compressed adiabatically, that is, without cooling during compression, the *useful* work is the same as in isothermal compression, but the actual work done in the cylinder (not including work lost by friction and leakage) is greater, or

$$3.463\ P_1V_1 \left\{ \left(\frac{P_2}{P_1}\right)^{0.29} - 1 \right\}.$$

The efficiency of blowing machines (i.e., the ratio of the air horse-power to the horse-power required to drive the machine) ranges from 95 per cent in the case of a slow-moving engine with large inlet and outlet valves, down to almost zero in poorly designed rotating machines. Centrifugal compressors have an efficiency under normal load of from 40 to 60 per cent (*see Fans*). A 39 by 84-inch positive blower, made by the Connersville Blower Co., is reported to have given an efficiency ranging from 68.5 per cent at an air pressure of 0.5 pound per square inch to 86 per cent at a pressure of 3.5 pounds per square inch, the displacement of air in each case being approximately 18,000 cubic feet per minute. The efficiency of steam-jet blowers is very low.

SPECIFICATION FOR BLOWER.*—The following memoranda are intended to assist in writing specifications. See also under *Fans* and article on *Specifications*.

Principal Characteristics and Conditions of Service.—Purpose of blowers.

Style and Description; Details of Construction.—Shall have horizontal, upward or downward discharge. Location of air outlet with reference to rotating parts. Hand or automatic closing of dampers when blower stops. How coupled to motor or engine, i.e., direct or belted. If direct driven, give details of coupler to disconnect blower from motor. Lubrication. Tools. Enclosure of moving parts to reduce danger.

Performance and Tests.—Cubic feet of air per minute. Air pressure, ounces or inches of water column at stated temperature.

ELECTRIC DRIVE OF COMPRESSORS.†—(*See also Motors, Industrial Applications of.*) As compressors of the reciprocating type must be driven at a low speed, the synchronous motor is well adapted for driving them, chiefly

* By W. A. Del Mar.
† By D. B. Rushmore.

because this motor operates normally at unity power factor and can be efficiently operated at leading power factors to counteract the lagging power factor due to induction motors driving other apparatus on the system. Slow-speed induction motors must be built with a large number of poles and will then operate at very low power factors with a comparatively low efficiency. Other reasons favoring the synchronous motor drive for this service are the steady load and the low torque required in starting, as a by-pass is generally provided so that the compressor works only against atmospheric pressure when starting. The motor should be able to be started from the alternating-current side and should for this reason be provided with the usual "squirrel-cage" winding. There is usually sufficient flywheel effect in the machine itself to keep within a reasonable angle of displacement, so that no trouble is experienced from "hunting."

For driving the centrifugal type of compressor, which requires a comparatively high speed, the synchronous motor is not as well adapted, and the best operation can generally be secured by the use of high-speed induction motors. For large units or where a low starting current is desirable the phase-wound type of motor should preferably be selected, although for smaller units the squirrel-cage type will as a rule prove satisfactory.

For direct-current installations compound-wound motors are generally used for driving reciprocating compressors and shunt-wound motors for the centrifugal type.

DIMENSIONS, WEIGHTS AND COSTS. — There is so great a variety of blowers and compressors that it is impossible in the space available to give a representative table of dimensions, weights and costs. The reader is referred to the manufacturers' catalogues and price lists. Representative manufacturers are the Ingersoll-Rand Co., the American Blower Co., the Sturtevant Co., and the Connersville Blower Co. (*See also Kent's Mechanical Engineers' Pocket-Book.*)

[Wm. Kent.]

BOILERS, STEAM. — (*See also Chimneys; Condensers, Steam; Conveyors; Draft, Mechanical; Feed-water Heaters; Fuels; Pipes and Piping; Power Stations; Pumps; Separators, Steam; Steam.*) The simplest form of boiler is a closed metal cylinder partly filled with water, with a pipe for the introduction of feed water, another pipe for the escape of steam and means for maintaining a fire under the boiler. Modifications of this elementary form are made: (1) for the purpose of insuring that as large a fraction as possible of the heat energy generated by the burning fuel shall be absorbed by the water and as small a fraction as possible shall be lost in the escaping hot gases and by radiation; and (2) for the purpose of increasing the heating surface and therefore the evaporative capacity of the boiler, with as great an economy of space occupied and of cost of the metallic structure as possible, without at the same time endangering the safety of the boiler, or decreasing its durability, facility for cleaning or other desirable qualities.

DEFINITIONS. — Certain special terms used in reference to boilers are defined below.

Boiler Horse-power. — This term was originally introduced to indicate the size of boiler required for an average reciprocating engine, the boiler being said to have the same horse-power as that of the engine. Due to improvements in the design of steam engines a boiler of a given horse-power rating may be ample to supply an engine (e.g., a compound condensing engine) of 3 times the rating of the boiler. The American Society of Mechanical Engineers has adopted the following definition:

A boiler horse-power is equivalent to the evaporation of 34.5 pounds of water per hour from feed water at 212° F. to saturated steam at the same temperature.

Adopting Marks and Davis's figures for the properties of steam (*see Steam*) 34.5 pounds of steam from and at 212° F. is equivalent to 33,479 B.t.u. per hour, or to an evaporation of 30.018 pounds from 100° F. feed-water temperature into steam at 70 pounds gage pressure.

It is customary in the trade to consider 10 square feet of heating surface as equivalent to a boiler horse-power, for stationary boilers. The term boiler horse-power is not used in connection with locomotive or marine boilers, and there is a tendency to discontinue its use for stationary boilers, expressing their size in square feet of heating surface, and their evaporative capacity in pounds of water evaporated from and at 212° F. per hour.

Equivalent Evaporation. — Factor of Evaporation. — For the purpose of reducing the results of a boiler test made under certain conditions of feed-water temperature and steam pressure and quality to a common standard, it is customary to use the equivalent evaporation from and at 212° F. as that standard. The pounds evaporated under actual conditions are multiplied by a "factor of evaporation," F, which is determined by the formula

$$F = \frac{H - h}{970.4},$$

in which H = total B.t.u. above 32° F. in 1 pound of steam at the actual pressure and degree of superheat, and h = total B.t.u. above 32° F. of 1 pound of the feed water. The values of H and h are given in steam tables (*see Steam*). If the steam contains x per cent of moisture, use for H in the above formula

$$H = H'\left(1 - \frac{x}{100}\right) + \frac{h'x}{100},$$

where H' is the total heat of saturated steam at the given pressure and h' is the heat of the liquid at the given pressure, as given in steam tables.

Boiler Efficiency. — The efficiency of the boiler alone is usually defined as the ratio of the number of B.t.u. absorbed by the water per pound of combustible *actually* burnt, to the number of B.t.u. in one pound of the combustible. The over-all efficiency of the boiler and grate is the ratio of the B.t.u. absorbed by the water per pound of *coal as fired* to the number of B.t.u. in one pound of this coal. This over-all efficiency differs from the efficiency of the boiler alone according to the amount of coal lost through the grates.

"Economy" or Water Rate. — Boiler efficiency is also frequently expressed in terms of the number of pounds of water evaporated from and at 212° F. per pound of combustible in the coal actually burnt (this corresponds to the efficiency of the boiler alone), or per pound of coal as fired (this corresponds to the efficiency of boiler and grate). The number of pounds of water evaporated from and at 212° F. per pound of coal is frequently referred to as the "economy" of the boiler, or its "water rate."

The relation between efficiency and economy may be expressed as follows.

Let ϵ = boiler efficiency, in per cent,
B = B.t.u. per pound of coal,
w = economy, i.e., the equivalent number of pounds water evaporated per pound of coal.

Then

$$w = \frac{B\epsilon}{97,040}.$$

For example, if the coal contains 10,000 B.t.u. per pound and the boiler efficiency is 70 per cent, then the economy is $10,000 \times 70/97,040 = 7.2$ pounds water per pound coal.

CLASSIFICATION OF BOILERS. — Boilers may be classified as *externally* and *internally fired*, *water tube* and *fire tube*, *through tube* and *return tube*, *horizontal* and *vertical*. An *internally fired* boiler is one in which the furnace is built inside of the boiler, and its roof and sides form a part of the heating surface of the boiler; the locomotive and Scotch marine, the Lancashire and the vertical-tubular boiler are of this type. An *externally fired* boiler is one in which the furnace is separate from the boiler itself and is usually placed underneath it, but sometimes at the side of it in a structure lined with fire-brick. A *fire tube* boiler is one in which the hot gases pass through the tubes, whereas the water is contained in an external shell through which the tubes pass. A *water tube* boiler is one in which the water is contained in the tubes and the hot gases pass around them. A *through tube* boiler is one in which the hot gases pass directly through the tubes from the fire to the smoke flue, whereas in a *return tube* boiler the gases are caused to pass under the shell containing the tubes to the farther end, thence upward through the "back connection," or rear of the setting and return through the tubes to the "breeching" or flue connection to the chimney. The term "return tubular" is applied only to fire tube boilers.

APPLICATIONS OF VARIOUS TYPES. — Externally fired *return tube* boilers in sizes up to 200 horse-power and for pressures up to 150 pounds per square inch are very commonly used. Boilers of this type are comparatively cheap and do not require expensive setting. In large power stations externally-fired *water tube* boilers are almost invariably used in this country. These boilers are built in sizes up to 2300 horse-power and for all practicable pressures. Babcock and Wilcox, Heine, Sterling and Wickes boilers are of the water tube type. In the first two makes the tubes are slightly inclined, in the third they are quite steeply inclined, and in the last they are vertical.

Selection of Type of Boiler. — In selecting the type of boiler to be used in any particular case the following points should be taken into consideration: (1) steam pressure desired; (2) space available; (3) danger of explosion; (4) liability to minor troubles which cause temporary stoppage; (5) durability; (6) ease of making repairs; (7) facilities for cleaning and removing scale and for inspection; (8) water-storage capacity; (9) rapidity at which steam can be raised; (10) steadiness of water level; (11) dryness of steam; (12) cost, including setting.

The question of economy of fuel is not generally dependent on the type of boiler, as the same economy may be obtained with all types provided. In order to secure maximum economy the following requirements are essential: (1) sufficient heating surface; (2) that the fuel can be thoroughly burned in the furnace, so that no unburned gases are allowed to reach the heating surface, and (3) that the path of the gases through the boiler is properly baffled so that they are not "short-circuited," leaving part of the heating surface out of the current.

DESIGN AND CONSTRUCTION. — The essential parts of the boiler in the case of a water tube boiler are the tubes, steam drums and mud drums, grates and setting. The tubes are usually 4 inches in diameter in large stationary boilers, and are usually more or less inclined. The steam drums are large cylindrical vessels which serve as a reservoir for the water and steam. The mud drums are arranged to collect a considerable part of the sediment formed by evaporation of the water. Suitable blowpipes are provided for draining off the water and for discharging the sediment and scale-forming material. The water level in the boiler is usually indicated by a gauge glass or try cocks, or both, connected either directly to the boiler shell or to a water column. Suitable manholes and handholes are provided to give access to the various parts of the boiler.

Heating Surface. — For maximum fuel economy with any kind of boiler it should be proportioned so that at least one square foot of heating surface should be given for every 3 pounds of water to be evaporated from and at 212° F. per hour. Still more liberal proportions are required if a portion of the heating surface has its efficiency reduced by: (1) tendency of the heated gases to short-circuit, that is, to select passages of least resistance and flow through them with high velocity, to the neglect of other passages; (2) deposition of soot from smoky fuel; (3) incrustation. If the heating surface is clean, and the heated gases pass over it uniformly, little if any increase in economy can be obtained by increasing the heating surface beyond the proportion of 1 square foot to every 3 pounds of water to be evaporated, and with all conditions favorable but little decrease of economy will take place if the proportion is 1 square foot to every 4 pounds evaporated; but in order to provide for driving of the boiler beyond its rated capacity, and for possible decrease of efficiency due to the causes above named, it is better to adopt 1 square foot to 3 pounds evaporation per hour as the minimum standard proportion.

For maximum commercial economy, taking into consideration not only the cost of fuel but also the interest, depreciation and taxes on the cost of the plant, a higher rate of driving may be required, even as high as 6 or 8 pounds per square foot of heating surface per hour at the time of maximum or peak load, if the high loads last only a few hours each day.

Measurement of Heating Surface. — The usual rule is to consider as heating surface all the surfaces that are surrounded by water on one side and by flame or heated gases on the other, using the external diameter for

Grates. — Three kinds of grates are employed, the stationary, the rocking or shaking, and the traveling grate. The grate bars are made of cast iron. Rocking grates have the advantage of permitting clearing the fire-bed of ash and clinker without opening the fire door and require less manual labor than the stationary grate. A traveling grate is one form of a mechanical stoker (*see Stokers, Mechanical*).

Grate Surface. — The amount of grate surface required per horsepower and the proper ratio of heating surface to grate surface are extremely variable, depending chiefly upon the character of the coal and upon the rate of draft. With good coal, low in ash, approximately equal results may be obtained with large grate surface and light draft, and with small grate surface and strong draft, the total amount of coal burned per hour being the same in both cases. With good bituminous coal, like Pittsburgh, low in ash, the best results apparently are obtained with strong draft and high rates of combustion, provided the grate surfaces are cut down so that the total coal burned per hour is not too great for the capacity of the heating surface to absorb the heat produced.

With coals high in ash, especially if the ash is easily fusible, tending to choke the grates, large grate surface and a slow rate of combustion are required, unless means, such as shaking grates, are provided to get rid of the ash as fast as it is made.

The following table is adapted from a more extensive one given in Gebhardt's *Steam Power Plant Engineering*.

Nature of plant	Number of plants	Character of fuel	Average ratio of heating surface to grate surface
Central stations	10	Illinois screenings, 15 to 20% ash	65
Central stations	14	Bituminous	60
Central stations	1	Bituminous	31
Central stations	9	Anthracite	40
Mfg. plants	20	Anthracite	35
Office building	6	Bituminous	48

Calculation of Required Heating Surface and Grate Area. — From the data given above the proper grate area and heating surface may be calculated as follows:

Example 1. — Steam required per hour at the "peak of the load," 6000 pounds; 3000 pounds ordinarily. Steam per pound of the poorest coal under the given conditions of feed-water temperature and steam pressure at maximum rate of driving, 6 pounds. This corresponds to $6000/6 = 1000$ pounds of coal per hour. Maximum rate of combustion under worst conditions, 25 pounds of coal per square foot of grate per hour. The required grate surface is then $1000/25 = 40$ square feet. Heating surface for maximum economy at ordinary driving will be $3000/3 = 1000$ square feet, requiring $6000 \times 3/3000 = 6$ pounds of steam per square foot of heating surface per hour at highest rate. Ratio of heating to grate surface, $1000/25 = 40$ to 1.

Example 2. Let 3000 pounds of steam be required per hour uniformly. The coal is of good quality so that 9 pounds of water will be evaporated per pound of coal when the rate of driving does not exceed 3 pounds of evaporation per square foot of heating surface per hour. The rate of combustion of this coal may be as high as 30 pounds per square foot of grate per hour, but to have more easy firing, 20 pounds is chosen. Then,

$$\begin{aligned}\text{Heating surface} &= 3000/3 = 1000 \text{ square feet;}\\ \text{Coal per hour} &= 3000/9 = 333 \text{ pounds;}\\ \text{Grate surface} &= 333/20 = 16.7 \text{ square feet;}\\ \text{Ratio of heating to grate surface} &= 1000/16.7 = 60 \text{ to } 1.\end{aligned}$$

Air Passages through Grates. — The usual practice is to make the air opening 30 to 50 per cent of the total grate area. With coal free from clinker much smaller openings may be used.

Flues and Other Gas Passages. — Rules are usually given making the area of gas passages bear a certain ratio to the area of the grate surface; thus a common rule for horizontal tubular boilers is to make the area over the bridge wall 1/7 of the grate surface, the flue area 1/8, and the chimney area 1/9.

For average conditions with anthracite coal and moderate draft, say a rate of combustion of 12 pounds of coal per square foot of grate per hour, and a ratio of heating to grate surface of 30 to 1, this rule is as good as any, but it is evident that if the draft were increased so as to cause a rate of combustion of 24 pounds, requiring the grate surface to be cut down to a ratio of 60 to 1, the areas of gas passages should not be reduced in proportion. The amount of coal burned per hour being the same under the changed conditions, and there being no reason why the gases should travel at a higher velocity, the actual areas of the passages should remain as before, but the ratio of the area to the grate surface would in that case be doubled.

Mr. Barrus states that the highest efficiency with anthracite coal is obtained when the tube area is 1/9 to 1/10 of the grate surface, and with bituminous coal when it is 1/6 to 1/7, for the conditions of medium rates of combustion, such as 10 to 12 pounds per square foot of grate per hour, and 12 square feet of heating surface allowed to the horse-power.

Boiler Settings. — The boiler proper is usually mounted in a brick setting with suitable iron buckstays. The setting also forms the walls of the furnace. Common red brick is usually employed for the setting except for those parts which are exposed to a sufficiently high temperature to require the use of fire brick. Sometimes a separate furnace, or "Dutch oven," directly in front of the boiler, is used.

OIL BURNERS AND FURNACES. — In burning liquid fuel in steam-boiler or other furnaces it is of the utmost importance that the fuel be completely atomized and that each minute particle be surrounded by sufficient air for its complete combustion. Failure in this results in the formation of smoke and soot. The following methods of injecting the oil and air into the furnace are used in connection with steam boilers:

(1) *Steam injection.* A fine jet of steam at high pressure is employed to inject both oil and air into the furnace. Furnaces fired by this method are very successful in burning oil without smoke, if the oil is not fed to the furnace at a rate faster than that for which the burner is designed. (2) *Air injection.* Air at about 40 pounds pressure per square inch is used to inject and atomize the oil. Burners of this type are very successful, and they give higher temperatures than steam injectors. The objection to them is the cost of the air-compressing machinery. (3) *Mechanical injectors.* The oil under pressure

delivered in a very fine spray. Some burners of this type have given excellent results. With these burners it is necessary to supply the oil under a high pressure, say from 50 to 80 pounds per square inch and to heat it before reaching the burner to a temperature of from 120° to 180° F. in order to reduce its viscosity.

More important than the burner is the furnace. It must be of sufficient size to give ample room for complete combustion of the gases formed by decomposition of the oil before these gases are allowed to be chilled by contact with the heating surfaces of the boiler. For economy of oil the air supply should be regulated so that the excess of air is not more than 50 per cent above that theoretically required for complete combustion.

SUPERHEATERS. — To obtain the advantages of superheated steam (*see Steam*), various forms of superheaters are employed. A superheater consists essentially of a number of small tubes, through which the steam is passed, arranged to be heated by the hot gases in the boiler or from some external source. In this country the superheater is nearly always placed within the boiler setting. Frequent cleaning of the exterior walls of the superheater tubes with steam is necessary to prevent the accumulation of soot. It is customary to provide for the flooding of the superheaters when the boiler is banked and when steam is being raised; this procedure may be undesirable when the feed water contains much scale-forming impurity, as superheater tubes are not readily cleaned internally.

PERFORMANCE OF BOILERS. — The number of boiler horse-power (i.e., the number of pounds of steam from and at 212° F. divided by 34.5) which can be obtained from a boiler depends upon the heating surface of the boiler, the grate area of the furnace, the quality of coal used, the method of firing, etc. Consequently the horse-power rating of a boiler is at best but an exceedingly rough indication of its capacity, and therefore the modern tendency is to rate a boiler in terms of the number of square feet of heating surface. If the horse-power rating is also given, this is usually taken arbitrarily for water tube boilers as the number of square feet of heating surface divided by 10; that is, 1 boiler horse-power is taken as equivalent to 10 square feet of heating surface. Some large modern boilers, however, are operated normally under conditions such that the boiler horse-power actually developed is twice the rating on this basis. Builders of fire tube boilers usually rate them on the basis of 11 to 12 square feet per boiler horse-power.

Boiler Capacity. — The capacity of a boiler may be expressed in terms of the boiler horse-power which may be obtained from it, or, more definitely, in terms of the number of pounds of water which can be evaporated in it. The capacity of a boiler, by which is meant the quantity of steam it will make in a given time, depends (1) upon the quantity of heat that can be generated in the furnace, and (2) upon the percentage of this heat that is absorbed by the boiler and not wasted in the chimney gases or by radiation.

The first essential of boiler capacity for a given heating surface is furnace capacity, and this depends chiefly upon three things, area of grate surface, quality of fuel and force of draft. It may also depend upon the kind of grate, as plain or shaking grate, or mechanical stoker; upon the roof of the furnace, whether formed of the heating surface of the boiler, or of fire brick; and upon the introduction of air above the fire in addition to that which passes through the grate. The second essential of boiler capacity is boiler efficiency. Other things being equal, anything that increases the efficiency of a boiler increases its capacity in the same ratio.

Factors Affecting the Efficiency of a Boiler. — Boiler efficiency depends: (1) on the quality of the coal (or other fuel) as regards its content of

moisture and volatile matter (*see article on Fuels*); (2) on the completeness with which the coal is burned in the furnace, before the gases of combustion touch the heating surface; (3) on the combustion being effected with the least possible excess of air, above 20 per cent excess being necessary to avoid imperfect combustion; (4) on the cleanness of the heating surface, inside and out; (5) on the proper baffling of the gases, so as to avoid short-circuiting; (6) on the heat lost by radiation; and (7) on the extent of the heating surface relative to the quantity of heat generated, or to the rate of driving of the boiler, as measured by the heat absorbed in a given time per square foot of heating surface (*see section on Heating Surface, below*). In general the efficiency of a boiler may be represented approximately by the equation

$$\epsilon = \frac{T_1 - T_2}{T_1},$$

in which T_1 is the temperature of the fire and T_2 the temperature of the chimney gases. The temperature T_1 is proportional to the heat generated in the furnace, assuming the specific heat of the gases to be constant, and T_2 to the heat loss in the chimney. The loss by radiation is not considered in the formula, but this is generally not over 2 to 3 per cent when a boiler is driven at a normal rate.

Values of Boiler Efficiency. — The *highest* efficiency that is obtained with ordinary boilers and furnaces, fired by hand, is about 79 per cent with anthracite and 76 per cent with bituminous coal. As high as 81 per cent may possibly be obtained with bituminous coal with very large boilers, provided with mechanical stokers, and 82 per cent with oil fuel. With economizers, heating the feed water by the waste heat of the gases from the boiler, the combined efficiency of boiler and economizer may be as high as 90 per cent.

The necessary conditions for obtaining these high figures of efficiency are: (1) that the coal is of good quality, low in moisture; (2) that the coal is burned uniformly and with uniform conditions of air supply, so that the grate is not obstructed by clinker or imperfectly covered by coal; (3) that the rate of driving does not exceed 3 pounds evaporation per square foot of heating surface per hour; (4) that the air supply does not exceed 20 pounds per pound of carbon burned; (5) that the combustion of the gases is completed in the furnace, so that no unburned gases touch the heating surface of the boiler and become chilled below the point of ignition; (6) that the path of the gases through the boiler is so baffled as to cause them to traverse uniformly all parts of the heating surface; (7) that the heating surface is free from soot and dust on the outside and from scale or grease on the inside.

The conditions of high efficiency above described are obtained only in the best-managed plants, where the chimney gases are constantly analyzed as a check on the air supply (*see below under Tests of Boilers*). In the average plant in everyday practice the efficiency may be anywhere from 10 to 30 per cent below the best possible.

Effect of Rate of Evaporation on Efficiency. — On the basis of 10 square feet of heating surface per boiler horse-power (34.5 pounds of steam from and at 212° F.) approximately 3 pounds of steam are evaporated per square foot of heating surface when the boiler is developing its rating at normal steam pressure and temperature. If there is sufficient grate surface and draft the evaporation may be increased to 6 or in emergency to 15 pounds of steam per square foot of heating surface. The efficiency, however, falls off with increased rate of driving. The following figures are taken from a test by D. S. Jacobus (*Trans. A.S.M.E., 1911*) on a large Stirling boiler (23,650 square feet of heating surface).

Equivalent evaporation per square foot =	3.24	3.40	3.72	4.18	5.22	5.62	6.40	6.67	6.75	7.29
Over-all efficiency =	81.2	81.0	80.3	79.2	77.1	77.9	76.4	76.7	75.6	75.8

Still higher rates of driving and the corresponding efficiencies are given below, these figures being taken from a test of Babcock & Wilcox boilers designed for the United States warships "Cincinnati" and "Wyoming" (*Industrial Engineering, March, 1911*). The results are as follows:

Equivalent evaporation per square foot =	8.42	8.75	9.03	9.58	10.1	10.5	13.7	14.8
Over-all efficiency =	70.4	70.6	72.1	68.2	70.1	71.0	64.5	63.3

These efficiencies are all exceptionally high for the given rates of driving, but the relative efficiencies for the different rates are representative of good average practice.

Thickness of Fire and Efficiency. — Too thin a fire results in excess of air and too thick a fire in a deficiency, unless sufficient draft is provided by means of fans or tall chimneys (*see Draft, Mechanical*). There are so many factors to be considered that the proper thickness for maximum economy in any particular case can be determined only from actual test. Under ordinary conditions of hand-firing the thickness of fire for best efficiency ranges from 6 to 12 inches.

Air Supply and Efficiency. — The air supply for maximum efficiency, all other conditions remaining constant, is about 17 or 18 pounds per pound of carbon.

With an air supply lower than 17 pounds the efficiency is likely to fall off, on account of imperfect combustion. If the air supply is greater than 20 pounds the efficiency falls off very rapidly, the excess air supply causing a reduction of temperature in the furnace and an increase of heat carried into the chimney.

Heat Balance and Distribution of Losses. — By the "heat balance" is meant a statement accounting for ultimate distribution of the B.t.u. in the fuel supplied to the boiler. Such a statement is usually made up as follows. The figures given illustrate the ordinary range for the various items.

HEAT BALANCE PER POUND OF COMBUSTIBLE

Item	B.t.u.	Per cent
1. Heat absorbed by the boiler	......	80–50
2. Loss due to heating moisture in coal	......	0.2–2.0
3. Loss due to heating moisture formed by the burning of hydrogen	......	0.5–4.0
4. Loss due to heat carried away in the dry chimney gases	......	12–30
5. Loss due to incomplete combustion of carbon (CO in flue gas)	......	0.0–3.0
6. Loss due to		
a. Unconsumed hydrogen and hydrocarbons (smoke and soot)	......	0.0–1.5
b. To heating the moisture in the air	......	0.2–1.5
c. To carbon lost through grate	......	0.5–3.0
d. To radiation	......	1.0–3.0
e. Unaccounted for	......	1.0–10.0
Total	11,000 to 15,500	100

The five items under 6 are frequently given as a single item.

TESTING OF BOILERS. — The principal observations made during an "evaporation" test of a boiler are pounds of water evaporated, pounds of coal fired, steam pressure and feed-water temperature. Records of the water evaporated and the coal fired should be made for each hour of the test if possible. The steam pressures and feed-water temperatures are recorded every half-hour or oftener, and averaged for the whole test. All conditions should as nearly as possible be the same at the end as at the beginning of the test. When the furnaces are hand fired, tests of 8 to 10 hours duration are usually sufficient, but when mechanical stokers are used it is difficult to obtain an equal quantity and condition of the coal in the furnace at the beginning and end of the test, and a large error in the results may be made if the test is much shorter than 24 hours. The average moisture in the coal should be determined and the ash and refuse should be weighed.

In all important tests the code prepared by a committee of the American Society of Mechanical Engineers (*Code of 1913*) should be followed. The principal data and results given in this code are as follows:

PRINCIPAL DATA AND RESULTS OF BOILER TEST.

1.	Grate surface (width ...., length ....)	sq. ft.
2.	Total heating surface	sq. ft.
3.	Date	
4.	Duration	hr.
5.	Kind and size of coal	
6.	Steam pressure by gauge	lb.
7.	Temperature of feed water entering boiler	° F.
8.	Percentage of moisture in steam or number of degrees of superheating	per cent or ° F.
9.	Percentage of moisture in coal	per cent
10.	Dry coal consumed per hour	lb.
11.	Dry coal consumed per sq. ft of grate surface per hour	lb.
12.	Equivalent evaporation per hour from and at 212°	lb.
13.	Equivalent evaporation per hour from and at 212° per sq. ft. of heating surface	lb.
14.	Rated capacity per hour, from and at 212°	lb.
15.	Percentage of rated capacity developed	per cent
16.	Equivalent evaporation from and at 212° per lb. of dry coal	lb.
17.	Equivalent evaporation from and at 212° per lb. of combustible	lb.
18.	Calorific value of 1 lb. of dry coal by calorimeter.	B.t.u.
19.	Calorific value of 1 lb. of combustible by calorimeter	B.t.u.

20. Efficiency of boiler, furnace and grate:

$$100 \times \left(\frac{\text{Item } 16 \times 970.4}{\text{Item } 18}\right) \ldots\ldots\ldots\ldots \text{ per cent}$$

21. Efficiency of boiler and furnace:

$$100 \times \left(\frac{\text{Item } 17 \times 970.4}{\text{Item } 19}\right) \ldots\ldots\ldots\ldots \text{ per cent}$$

Flue Gas Analysis and Heat Balance. — See Kent's *Mechanical Engineers' Pocket-Book* and Gebhardt's *Steam Power Plant Engineering*.

SPECIFICATIONS FOR STEAM BOILERS. — As nearly all steam boilers are now made by large manufacturing concerns who have their own specifications as to details of construction, quality of material, etc., it is rarely the case that an engineer of a power plant or a consulting engineer is called on to make an original design of a boiler or to furnish detailed specifications for one. What is usually done is to call for bids on general specifications, naming the quality of coal to be used, the kind of furnace or stoker, the horse-power to be developed (34.5 pounds of water evaporated from and at 212° F. = 1 h.p.), when the boiler is driven at a rate not to exceed 3.5 pounds per square foot of heating surface per hour, evaporated from and at 212° F., and the overload capacity desired for higher rates of driving, or "the peak of the load." The bids received are then tabulated as to the details, such as heating surface, grate surface, size of combustion chamber, size of tubes, diameter of shell, quality of steel, style of riveting, factor of safety, space occupied, guarantees of capacity and economy, etc., and a selection made of the boiler that appears to be the most suitable for the location. Of two boilers that have the same heating surface the one that has the largest grate surface is the one that has the greatest overload capacity, if the draft is the same in both cases. Guarantees of capacity and economy may be disregarded when bids are for ordinary forms of boilers and furnaces, for the capacity and economy of two boilers of the same size of grate and heating surface will be practically the same whatever the type or form of the boiler, but they will vary greatly from causes independent of the boilers themselves, such as quality of coal, method of firing, kind of furnace, size of combustion chamber, etc.

OPERATION OF BOILERS. — To obtain the best results from boilers, considerable care must be paid to the firing and regulation of air supply.

Firing. — There are three common methods of hand firing: (1) the alternate in which fresh coal is fired on one side of the grate at a time, the combustion of volatile matter being assisted by the heated air passing through the other side; (2) the spread-firing, in which small amounts are spread thinly over the entire fire bed; and (3) the coking, in which a thick bed of fresh coal is fired directly in front of the door and allowed to coke, after which it is pushed back into the furnace. The best method for any particular kind of fuel, style of furnace and rate of driving should be determined by experiment.

Mechanical stokers (*see Stokers, Mechanical*) afford the following advantages: viz., the uniform feeding of coal, the close regulation of the air supply at all times, and consequently smokeless and efficient combustion with a wide range of loads, and a great reduction of labor cost in handling and firing fuel. In small plants with poor load factors the expense of installation is generally considered prohibitive, but in plants of 1500 kilowatts or more a considerable net annual saving can usually be obtained.

Air Supply. — (*See also Chimneys; Draft, Mechanical.*) The extent of the flue losses is determined by the amount of gas discharged, the temperature at which it is discharged, the amount of incompletely burned gas discharged and the amount of latent heat carried away in water vapor. The minimum economic amount of flue gas would obtain with the amount of air supplied to the fire exactly equal to the theoretical requirements of complete combustion. The admission of less air tends to the production of CO. More air dilutes the flue gas, increases the total amount of gas rejected and, in the same ratio, increases the amount of heat rejected, the stack temperature remaining the same. The theoretical air supply per pound of combustible (*see Fuels*) is approximately 12 pounds, but since the air and fuel cannot be mixed with perfect intimacy it is necessary to considerably increase this amount to prevent the formation of CO. See above under ***Air Supply and Efficiency***.

CO_2 Recorders. — The per cent of CO_2 in the flue gas is an index of the air excess, provided combustion is complete. With perfect combustion and no excess air 20.9 per cent CO_2 should be obtained with pure carbon as fuel, or 18.6 per cent with a fuel composed of 95 parts C and 5 parts H. In practice more air must be supplied and 14 per cent CO_2 represents about the upper limit which should be attempted. 12 per cent CO_2 is good, 10 per cent fair and 8 per cent poor. Several types of CO_2 recorders have been devised. If properly maintained and interpreted they form a valuable check on the regulation of the air supply. Their indications, however, give no clue to the presence of CO, and are directly significant only when the formation of CO is prevented.

Flue-gas Temperature. — Because of the great heating surface which would be required it is not practicable to reduce flue-gas temperature to less than 75 degrees above the feed water. Economizers or flue-gas feed-water heaters (*see Feed-water Heaters*) assist in lowering the temperature of discharge but add considerably to the space required, increase the cost of installation and maintenance and increase the total draft required. Without economizers it is seldom economical to attempt to reduce the gas temperature below 450° F.

Smoke represents a minor element of loss *per se*, seldom exceeding 1 per cent, but it is generally an index of inefficient combustion. Smoke is usually due to a poorly regulated air supply, an imperfect mixture of air and fuel, or the too-rapid volatilization of hydrocarbons and their premature chilling in a half-burned state. The absence of smoke, however, is not a final index of efficiency, for the air supply may be excessive. See also article on *Smoke Prevention*.

Feed Water. — (*See Feed-water Heaters; Pumps and Pumping Engines.*)

Cleaning Tubes. — The tubes of a boiler should be kept clean, both internally and externally. For blowing the soot off the external surface the tubes of water tube boilers or off the internal surface of the tubes of fire tube boilers a steam jet blower is ordinarily used. For removing scale from the interior of water tubes different forms of scrapers or chippers are used, also rotary cutting devices driven at a high speed by steam, water or other power. For removing scale from the water side of fire tubes of horizontal tubular boilers the usual method is the operation of chipping and hammering by a man working inside of the boiler. Sometimes the scale is softened by the use of soda or other chemicals, before chipping, and a strong jet of water from a hose assists in detaching the scale. In locomotive practice it is often necessary to cut the tubes out of the boiler and run them through a cleaning machine, and then to weld a piece of each tube on one end to restore its original length, and to reset the tubes in the boiler.

DIMENSIONS OF BOILERS. — An ordinary fire tube boiler occupies a floor space of from 1.5 to 2.0 square feet per boiler horse-power (on the basis of 12 square feet of heating surface per horse-power): A water tube boiler occupies from 0.5 to 1.0 square foot of floor space per boiler horse-power (on the basis of 10 square feet of heating surface per horse-power). With either type the height ranges from as low as 7 to as high as 30 feet depending not only on the horse-power but also on the style, whether horizontal or vertical. One boiler is sometimes placed directly on top of another, making a "double-deck" arrangement. For complete dimensions see the manufacturer's catalogues.

COST OF BOILERS. — The selling price of boilers per rated horse-power (10 square feet of heating surface = 1 horse-power) ranges from about $8 to $25, depending upon the size, the pressure they are to sustain, the style and design, etc. The lowest prices named are for large-sized ordinary horizontal tubular boilers (fire tube) for low pressures. For power plants of 1000 horse-power and over the price will range usually between $10 and $15 for pressures

not over 150 pounds per square inch. For higher pressures and for boilers provided with superheaters the prices will be higher. For boilers of less than 100 horse-power the price per horse-power increases as the size decreases. The prices named are for the boilers with the usual fittings of grates, steam and water gauges, blow-off and stop valves, on board cars at the boiler works, and do not include the cost of erection nor of brickwork, flues or chimneys. (*See also Power Station.*)

C. H. Benjamin (*Eng., N. Y., Nov. 15, 1902*) gives the following rules for estimating the cost of boilers; P = boiler horse-power; the cost is in dollars.

(1) Horizontal water-tube boilers, 125 pounds pressure, 10 square feet of heating surface per boiler horse-power,

Cost of boiler $= 500 + 9.20\,P$.
Cost of setting $= 400 + 0.80\,P$.

(2) Vertical water tube boiler as in (1),

Cost of boiler $= 500 + 8.50\,P$.

(3) Horizontal return tubular boilers, 12 square feet of heating surface per horse-power,

Cost of boiler $= 100 + 6.50\,P$.
Cost of setting $= 300 + 0.70\,P$.

[WM. KENT.]

BONDS, RAILWAY TRACK. — (*See also Third Rail Systems; Trolley Systems; Wires and Cables.*) Rail bonds are electrical conductors for bridging the joints of rails. They consist either of a series of thin strips of annealed copper, or of one or more cables of copper wire, the ends of which are usually pressed or cast into solid copper terminals. Ribbon is more compact, but stranded wire is more flexible; the latter should always be used if space permits. Sometimes the terminals are made by upsetting the ends of a stranded conductor, so as to form a crude bond head. The terminals of the headed bond are then heated to a welding heat in furnaces, and pressed to the proper size and shape, the separate wires in the terminals becoming a solid mass of homogeneous copper. After being cleansed of all foreign substances the terminals are shaved to the proper size.

TYPES OF BONDS. — Bonds may be classified, according to the method of fastening them to the rail, as soldered bonds, brazed bonds and bonds applied by mechanical pressure.

Soldered Bonds (Figs. 1 and 2) usually consist of a series of thin strips of annealed copper with tinned terminals as shown in Figs. 1 and 2. They are

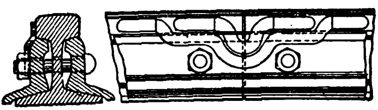

Fig. 1.

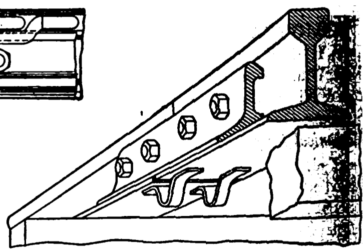

Fig. 2.

soldered direct to the head, foot or web of the rail. One or more bonds per joint may be used.

Brazed Bonds resemble soldered bonds except that the terminals are enveloped in brass. They are brazed or welded to the rail by heat generated electrically in a carbon electrode which constitutes one jaw of a clamp holding the bond against the rail.

Expanded and Compressed Terminal Bonds. — Bonds fastened to the rail by mechanical pressure may be divided into two general classes, expanded terminal and compressed terminal bonds.

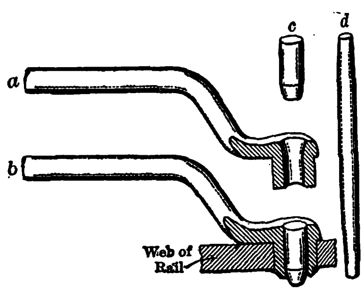

Fig. 3.

Pin-expanded Terminal Bonds (Fig. 3) have their heads drilled with an axial hole, through which a tapered steel pin *d* is driven, forcing the copper outward and against the steel. This type of bond is fastened to the web of the rail.

Compressed Terminal Bonds (Figs. 4 and 5). — There are two kinds of compressed terminal bonds, in one of which direct pressure is applied at both

ends of the head, and in the other, at one end only. The first type of bond is usually applied to the web of the rail by means of a heavy screw or hydraulic press (Fig. 8) which engages the bond head and causes it to compress longitudinally and expand laterally as the pressure is applied, bringing the copper into

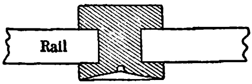

Fig. 4.

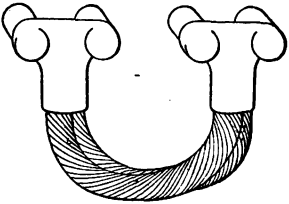

Fig. 5.

firm contact with the steel and spreading the projecting end of the terminal into a button-shaped rivet-head, as shown in Fig. 4. The second type of bond (Fig. 5) is applied only to the head of the rail, the terminal lugs being set in holes therein and expanded into contact by means of hammer blows.

Compressed Terminal Soldered Bond. — A type of bond which has been found very successful at the Detroit River Tunnel for third-rail work is a compressed terminal head bond soldered to the rail. The combination of mechanical adhesion and soldering has resulted in a bond of unusual durability. (*H. B. P. Wrenn.*)

Plastic Bonds. — In addition to the types of bonds described above, there is the plastic bond which in one form consists of a copper plate with amalgamated terminals pressed against amalgamated surfaces of the rail by the fish-plate. In another form it consists of an amalgamated copper plug set in a hole drilled vertically through the rail head and into the fish-plate.

Exposed Versus Concealed Bonds. — Whether soldered, brazed, expanded or compressed, bonds may be either exposed or concealed (Fig. 6) under the fish-plates. The former condition is preferable, if there is no likelihood of theft, as it permits inspection to be easily made. Where the bonds are exposed to theft, as, for example, on track rails unprotected by paving, concealed bonds are almost a necessity.

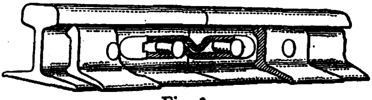

Fig. 6.

While concealed bonds are necessarily applied to the web of the rail, exposed bonds may be applied to the foot or head. Head bonds have the advantage of greater contact surface at the terminal studs, while foot bonds are less exposed to mechanical violence. Web bonds, unless concealed, have to be excessively long in order to span the fish-plates.

USES OF VARIOUS TYPES OF BONDS. — Bonds are used for track rails, third rails and girders of elevated and subway lines. Soldered bonds and compressed terminal head bonds find their best application in third-rail work, where good electrical contact is of greater importance than mechanical strength. Expanded terminal web bonds, especially of the concealed type with two stranded conductors, are regarded as the best for heavy track work, where mechanical strength and ease of installation are of the utmost importance.

SUBSTITUTES FOR BONDING.— Several efficient substitutes for bonding are now in use, such as electrical welding, cast welding, Thermit welding and the "Romapac" continuous rail system.

Electrical Welding is performed by clamping an iron bar to the web of the rails, and bringing the bar and the neighboring part of the rail to a white heat by means of an electric current.

Cast Welding is accomplished by setting a mold around the rail joint and pouring molten iron around it. The Thermit process is a modification of this, the iron being liberated at a white heat from a mixture of iron oxide and aluminum, which is ignited in a crucible.

Romapac Continuous Rail System (Fig 7). — This system differs from all forms of welding in not requiring heat at the joints, adhesion being obtained by a process of cold rolling. The rail consists of two pieces, a head and base, the head being provided with depending flanges which are rolled or crimped on to the base after the latter has been laid. The head and base pieces are staggered as shown in Fig. 7, thereby affording a continuous electrical path through the steel.

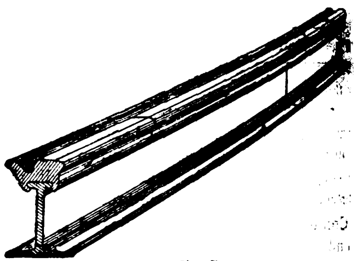

Fig. 7.

SELECTION OF TYPE AND SIZE OF BOND. — Considerations determining the choice between concealed and exposed bonds are liability of theft, electrolytic corrosion, facility of inspection and injury to fish-plate bolts of old rails.

The choice between mechanical adhesion and soldering depends largely upon the importance of rapid installation, the mechanical stresses to be withstood in service, and the facilities for the use of drills, presses, etc.

Single vs. Double Bonding. — Joints are sometimes bonded with one and sometimes with two bonds. Double bonding has the advantages of less chance of complete failure and greater carrying capacity for a given cross-section of copper. It, however, has the disadvantages of being more expensive and giving uncertain results in testing.

Selection of Cross-sectional Area of Bond. — The cross-sectional area of a rail bond should, as a rule, be not greater than is necessary to keep its temperature at a safe working amount, unless greater area is required for mechanical strength. The resistance of the bonded joint is of secondary importance unless very high, because the resistance of the joints is usually a mere fraction of the total track-rail resistance (*see below*).

Carrying Capacity of Bonds. — The carrying capacity of rail bonds is not very well known as the manufacturers do not supply any data on this subject for their various products. The excellent heat conductivity of copper and the large heat storage capacity of steel rails tend to make the carrying capacity of bonds in cold weather considerably greater than that of free wire of the same size, especially if the bonds are short. In hot weather, however, the rails and consequently the bonds are likely to become hot from exposure to the sun's rays, thereby reducing the effective carrying capacity of the bonds.

Tests to determine the ultimate carrying capacity of soldered bonds indicated that a 500,000 circular mil bond of the type shown in Fig. 1 will carry 3500 amperes continuously without injury, but will melt off in 5 or 10 minutes at 10,000 amperes. On the basis of this test assuming the cooling surface per unit

length of a bond to be proportional to the square root of its cross-section, the safe carrying capacity of a bond of A circular mils cross-section is

$$I = \frac{A}{5.6\sqrt[4]{A}}.$$

Or, the cross-section required for a given current is

$$A = 10\, I \sqrt[3]{I}.$$

Resistance of Bonds.—The total resistance of a bond is the sum of the resistances of the copper in the bond and the contact resistance between the body of the bond and the terminals and the contact resistance between the terminals and the rail. The following table gives the resistance of a well-bonded joint at 75° F., including the body resistance and the two contact resistances at each end.

RESISTANCE OF BONDED JOINT IN MICROHMS (10^{-6} OHMS)

Size A. W. G. or B. & S. and C. M.	Diameter of terminals, inches	Length of bond in inches, between centers of terminals							
		9	12	15	18	24	30	36	42
0	5/8	28	33	39	44	55	65	76	87
00	5/8	32	39	46	52	66	80	93	106
000	3/4	38	46	55	63	80	97	114	131
0000	7/8	44	54	65	75	95	116	136	157
250,000	7/8	50	62	75	87	111	136	160	185
300,000	1	60	75	91	107	137	169	200	230
400,000	1	72	91	112	131	171	210	250	290
500,000	1	87	112	137	162	211	260	310	360

Bonding Efficiency and "Equivalent" Length of Joint.—The bonding efficiency* of a bonded rail system (having one bonded joint to each rail length) is the ratio of its conductance to that of an equal length of perfectly continuous rail without any breaks or joints. By "equivalent" length of a joint is meant the length of continuous rail having a resistance equal to that of the bonded joint. Let

B = bonding efficiency,
l = distance in feet measured along the rail between centers of bond terminals,
l' = equivalent length of bonded joint in feet,
L = length in feet of a full rail section,
r = resistance of rail per foot,
R_j = resistance of bonded joint.

Then

$$l' = \frac{R_j}{r},$$

$$B = \frac{1}{1 + \frac{l' - l}{L}}.$$

* The efficiency of individual bonds is sometimes stated as the ratio of the distance along the rail between centers of bond terminals to the equivalent length $= l/l'$.

For values of *r* see article on *Rails*. The equivalent length of a properly bonded joint ranges from 1 foot to 6 feet, depending upon the size of rail, number and cross-section of bonds, length of bond, etc. (*See also section on Rebonding, below.*)

It is common practice to bond a joint with a bond having one-half the conductance of the rail. Hence for a 12-inch bond, and 30-foot rail section, assuming 9 inches between terminals measured along the rail, $l = 0.75$ and $l' = 2$, giving a bonding efficiency of 96 per cent.

In the Romapac system the resistance of the completed rail is usually less than that of an ordinary rail of the same cross-sectional area, because the peculiar shape of the rail necessitates a rolling mill process which lowers the resistivity of the rail metal without changing its chemical composition.

Selection of Length of Bond. — The length of concealed bonds is necessarily determined by the dimensions of the rail and fish-plate, and by the bolt-hole drilling. The length should never be less than ten inches for single bonding, and should generally be greater, it being usual practice to place the terminals between the first and second bolt holes. In double bonding it is customary to place one terminal of each bond between the first and second bolt holes of each rail, and the other terminals beyond the second bolt holes. It is not unusual to use concealed bonds 2 feet long for double-bonded rails on electrified steam roads. Exposed bonds are usually made as short as is consistent with the flexibility requisite to withstand vibration and other rail movements.

Effect of Vibration and Expansion of Rails. — The continual bending of a copper wire or ribbon will cause local hardening and crystallization of the metal, and eventually lead to fracture. It is, therefore, important to save track bonds from vibration as much as possible, and they should be initially designed to withstand the vibration they are likely to experience in use. The best way to accomplish this is to use long thin wires of soft annealed copper entirely free from surface imperfections.

According to the A. S. & W. Co., Cat. No. 3, wires of from 0.040 to 0.045 inch diameter give the best general service for short bonds.

Concealed ribbon bonds, and to a less extent wire bonds, frequently break at the loop between rail bolts, first, because the operation of crimping slightly hardens the copper in the loop, and second, because the travel of the rails, due to their expansion and contraction, is wholly taken up in the loops, causing the copper to crystallize and break at this point. Of course this action is aggravated by any severe jarring or vibration of the joint (*C. R. Sturdevant, Proc. Am. El. Ry. Assn., 1911, p. 756*).

SPECIFICATIONS. — (*See also article on Specifications and Contracts.*) Specifications for rail bonds should state the exact service conditions under which the bond is to be used, the style of adhesion desired, the part of the rail they are to be applied to, the style of conductor (ribbon, solid wire or strand), the cross-sectional area, the contact area of the stud, the formed length between centers of terminals, and the fish-plate and bolt layout, if the bonds are to be concealed.

INSTALLATION. — The foremost consideration in the installation of bonds is the cleanliness of the bonds and bond holes, or other adhesion surface. Unless this is secured the bonds will be electrically defective whatever their mechanical strength may be.

Soldered Bonds. — The rail surface is brightened by means of a carborundum or emery wheel, then tinned using an acid flux. The bond is then clamped in place and the rail and bond heated by means of a blow-torch, to a temperature at which the solder will melt and cause the bond to adhere firmly

Brazed Bonds. — The preliminary processes are the same as for soldered bonds except that a special clamp is used, the terminals of which are the electrodes of an electrical circuit, one being of copper and the other of carbon.

The surface of the rail being previously ground bright at the point where the weld is to be made, the brass-enveloped bond terminal is placed in position against the rail at this point, held there and pressed against the rail by the carbon electrode, the copper electrode being in contact with the opposite side of the rail. The current on passing from one electrode to the other, traverses the bond terminal and rail, the carbon becoming incandescent. The incandescent carbon pressing the copper against the rail quickly transmits sufficient heat at exactly the point where it is required, to produce the weld. To make a weld, the current is applied for a period of from 45 seconds to two minutes, depending on conditions.

Welding Outfit. — It is claimed by the manufacturers (The Electric Railway Improvement Co., of Cleveland, O.) that an average of over 100 bonds per day are readily installed by their car operating with four men, a bonder and three helpers. This car is about 6 feet, 10 inches long by 5 feet, 10 inches wide and carries an 18-kilowatt rotary converter and transformer, with the necessary apparatus for their safe operation. To weld an average-sized rail bond to the rail, an alternating current of about 2000 amperes at 5 volts is employed. On d-c. railways this is obtained by converting and transforming about 20 amperes at 500 volts taken from the trolley wire.

Pin-expanded Bonds. — The rail is drilled, usually through the web, with or without lubricant, using some form of drill especially adapted to this service. Drilling without lubricant has the advantage of giving a perfectly clean hole, but is believed by some to cause excessive wear of the drills. It is doubtful, however, whether the small amount of oil which would be used could be kept constantly at the cutting edges, the only places where it would be useful. Dry drilling has been found successful on many railroads. Advocates of lubrication are divided over the choice of lubricants, some preferring soapy water or caustic alkali solution, and some a clean lard oil. If oil is used, it should be wiped out with a clean cloth saturated with gasoline. According to the A. S. & W. Co., Cat. No. 3, oil lubrication will increase the joint resistance less than 3 per cent. Lubricants containing water are likely to cause rust, especially if the drilling gang precedes the bond installers by any considerable time. The hole having been drilled, the bond head is inserted into it and a long taper punch lubricated with grease is driven entirely through the terminal. Then a short drift pin is driven home, as shown in Fig. 3. The diameter of the hole is usually increased about 1/8 inch by the expansion process. From 100 to 200 bonds may be installed with one taper punch before it is worn down to an appreciable extent.

This type of bond requires a smaller equipment in tools and materials than most other types and does not necessitate the use of any apparatus which obstructs the track and thereby endangers traffic.

Compressed-terminal Web and Foot Bonds. — The drilling having been performed as for a pin-expanded bond, and the bond heads inserted into their respective holes, a screw or hydraulic compressor, as shown in Fig. 8, is applied at both ends of the bond head, the conical point of the press fitting into the conical depression of the bond. Pressure is applied, either until a collar on the ram touches the rail, or until the head of the bond acquires the proper shape. Where no collar is used the point of the press (if of the screw type) sometimes cuts into the bond head; this may be avoided by placing a small amount of flake graphite mixed with oil in the depression of the bond head.

Compressed-terminal Head Bonds. — A four-spindle drill is used to drill four holes simultaneously in the rail heads. It is important to avoid drilling

the holes too deep lest the copper should not touch bottom and therefore be unable to expand laterally. If, on the other hand, the hole is too shallow, expansion will occur too soon.

Pressure and Contact Resistance. — It has been found by P. M. Hall, P. C. Smith and C. B. Starbird (*St. Ry. Jour., Sept. 14, 1907*) that the pressure

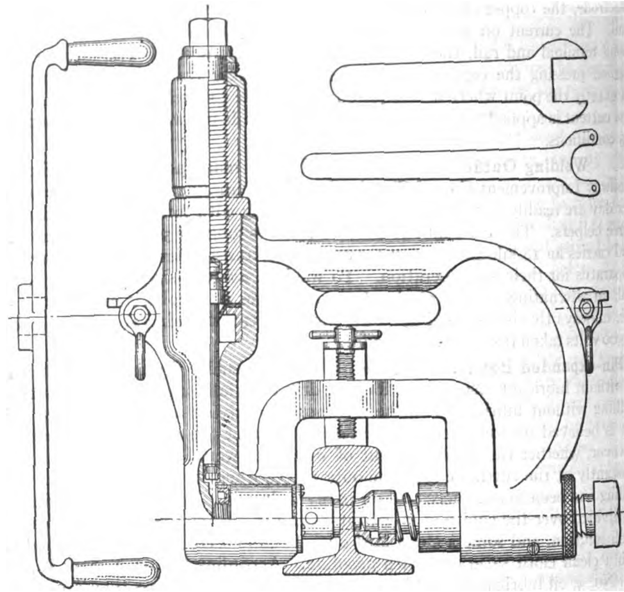

Fig. 8.

of a compressed-terminal rail bond against the steel rail, which gives a reasonably low-resistance value, is from 25,000 to 30,000 pounds per square inch of contact surface. To obtain this pressure a compressor giving a direct pressure of 25 tons per square inch of terminal steel section is required. This pressure being within the elastic limit of steel, the metal of the rail does not take a permanent set. Furthermore, if the contact surface of the bond terminal be increased, no appreciable decrease of resistance will occur unless the pressure is correspondingly increased. The contact resistance between annealed cast copper and steel is from 30 to 60 per cent higher than the resistance between annealed rolled copper and steel.

The copper of a bond head is hardened by the pressure it is subjected to, and, like the steel, is distorted within its elastic limit, causing the surfaces to adhere even if the pressure is reduced to one-third its original value, say 10,000 pounds per square inch. Between these two pressures, the electrical resistance does not vary. Expansion due to heat, therefore, has no effect upon the resistance of bonds.

TESTS AFTER INSTALLATION. — Every rail bond in service should be periodically tested and a complete record of the tests kept. The frequency of the tests will depend upon local conditions, once in 9 months being an average

of 14 urban railways, and once in 12 months an average of 11 interurban railways (*see Proc. Am. El. Ry. Assn., 1911, p. 751*).

Resistance Test. — The usual method of testing is to measure the drop of potential across the bonded joint and find simultaneously the length of continuous rail in which the same drop occurs, i.e., the "equivalent" length of the bonded joint. Several ingenious instruments have been devised for making this comparison with ease and accuracy.

Differential Voltmeter Method. — The most accurate type consists of a differential voltmeter and three contact pieces for attachment to the rail. One winding of the differential voltmeter is connected to a pair of contact pieces A and B, which are placed in contact with the rail just over the centers of the bond terminals, see Fig. 9, and the other winding to a pair of contact pieces B and C, which span a variable length of continuous rail. The distance BC is varied by moving the contact C until the voltmeter shows no deflection. This indicates that the potential drop between A and B is equal to that between B and C, or in other words, that a length of continuous rail has been found which has the same resistance as the bonded joint. The tester should make sure that there is current in the rail while he is making the test.

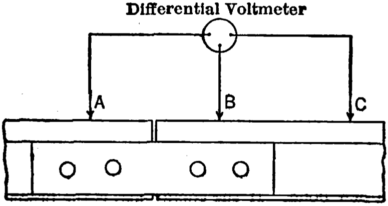

Fig. 9.

Conant Bond Tester. — R. W. Conant (Cambridge, Mass.) makes a bond tester in which the balancing is done by sound. A clockwork interrupter, an induction coil, and a telephone receiver is connected across a Wheatstone bridge (*see Bridges, for Electric Measurements*). The interrupted current causes sounds in the telephone receiver, which sounds diminish and disappear when the drop in the rail is balanced, by the bridge adjustment, to equal the drop across the joint. This type of apparatus has the advantage of being independent of the traction current in the rails, and is, therefore, constant in its sensitiveness.

Herrick Test Car. — A. B. Herrick has devised a recording instrument, which being placed on a car, is able to test the bonding of a railroad while running the car over it. The Herrick test car carries autographic recording apparatus, which measures by means of millivoltmeters, the potential drop across each joint, recording on sensitized paper by an electric spark, the scale of the record being usually about 1 inch to 60 feet of track. Wire-brush contacts made of steel of composition similar to that of the rail measure the drop across joints through which low-voltage current is circulated from a small motor generator set on the car, consisting of a 7½ horse-power 600-volt compound-wound motor direct connected to a 5-kilowatt 5-volt compound-wound generator and a small exciter. Some of the Herrick cars are equipped with sets, consisting of a 5-horse-power 600-volt compound-wound, 1200 r.p.m. motor, direct connected by flexible insulated coupling to a 2½-kilowatt compound-wound 2- to 6-volt generator, the motor and generator being of open type. The car trucks are insulated from each other, current passing through the rail from one truck to the other, while the bond is under measurement. The apparatus can also automatically mark bad bonds by squirting paint on the rail.

The advantages of this method of testing are as follows: 1. Uniform impressed low-voltage current through joints while testing; 2. Heavy car passing

over joint breaks any transient connection made by fish-plate; 3. Autographic record produced by the bonds themselves of their condition.

Mechanical Strength. — The mechanical adhesion of soldered bonds may be tested by means of a lever as shown in Fig. 10. It may be used as soon as the terminals are cool. The operation of testing consists simply in submitting each bond terminal to a predetermined pull. A properly soldered bond should stand a shearing force of 1200 pounds per square inch of contact. Calling S this shearing force per square inch, A the square inch of contact, and P the pull, as registered on the balance, then

$$P = \frac{ASl}{L}.$$

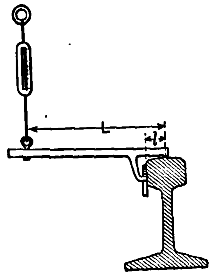

Fig. 10.

REBONDING. — The resistance at which a joint should be rebonded depends upon how much potential drop is permissible in the tracks, and upon the relative cost of the energy loss and the cost of rebonding. The latter, in turn, depends upon the probable life of a new bond. If the energy loss is the primary consideration, the resistance at which rebonding becomes economical is given by the formula below.

Let

R = amount by which the resistance of the existing bond has increased over that of a new bond, ohms,
B = cost of rebonding once, dollars, allowing credit for scrap material,
I = root-mean-square current in the bond, amperes,
C = cost of an increment of energy, dollars per kw. hour,
T = expected life of the bond in days, i.e., the number of days in which its resistance is expected to increase R ohms, or in which it is to be removed for any reason whatsoever. This may be estimated from previous experience on the railway under consideration, the usual limitations being the life of the rails to which they are attached, corrosion by electrolysis, fracture due to crystallization and loosening of the terminals.

Then it is economical to rebond if R is equal to or greater than

$$\frac{B}{0.024\,I^2CT}.$$

It is usual to state the resistance of bonds in terms of the number of feet of rail having the same resistance. Let r be the resistance of the rail in ohms per foot; then the increased resistance R will be represented by an increased length, expressed in feet, equal to $\frac{R}{r}$.

It should also be noted that bonds in different parts of a railway system carry different amounts of current, those nearer the station bus carrying more than those at comparatively remote points. Hence, the economical resistance at which to rebond is less the nearer the bond is to the bus, a consideration that complicates the use of the above formula. Furthermore, as the economical resistance is inversely proportional to the square of the current, a slight error in the estimation of the root-mean-square current will lead to a considerable error in the resistance. Such errors are unavoidable, a circumstance that, taken in conjunction with the probable error in the estimated life, renders the above formula a mere approximation. It is, therefore, usual for railway companies

to select some arbitrary total resistance at which to replace their bonds. In the Proc. Am. Elec. Ry. Assn., 1911, this resistance is given by 22 railways in terms of the equivalent length of continuous rail. This length ranged from 2 to 12 feet, with an average of 6.6 feet.

REPAIRS. — If a soldered bond becomes loose, it may often be resoldered, but defective bonds of other types are usually scrapped, unless the defect is of a very trivial nature. Pin-expanded bonds may, however, be reëxpanded into larger holes, but with some loss in efficiency. Soldered bonds entail a comparatively large and increasing expense for repairs when applied to track rails, in spite of the fact that no failures may occur for several months after installation.

COSTS. — The cost of bonding is extremely variable, depending upon the type and size of bond, cost of labor, etc. The following cost data should therefore be used with caution.

COST OF BONDING

	Cost per joint		
	Labor	**Material**	**Total**
a. 2-500,000 C.M. bonds soldered to head of third rail................	$0.66	$1.23	$1.89
b. 2-500,000 C.M. pin-expanded concealed bonds applied to track rail.	0.69	2.05	2.74
c. 2-400,000 C.M. compressed terminal concealed bonds applied to track rail...............................	....	....	1.90
d. 2-0000 bonds of same type as *c*......	0.50	1.00	1.50

Note. — In *a* and *b* the item for material includes inspection and the labor item includes foreman's salary; solder, acids and tools, not included.

[W. A. Del Mar.]

BRAKES AND BRAKING SYSTEMS. — (*See also Cars, Electric; Railways, Energy Requirements for.*) In order to stop a car or train a torque must be applied to the wheels in a direction opposite to the direction of motion of the car. This may be accomplished by applying a frictional retarding force to the wheel rims, by applying a retarding force to the axle by means of a magnetically operated friction clutch, by applying a reverse torque to the axles by operating the motors as generators, or by applying a frictional force to the rails directly by a "track brake." The method of applying a retarding frictional force to the wheel rims is the most general one and lends itself most readily to the system of manipulating the brakes by compressed air. This system has done much to improve the safety of travel on railroads. The other methods have all been tried and some have been put into practical operation, but only to meet special local conditions.

FRICTIONAL RESISTANCES IN BRAKE-SHOE SYSTEM. — The application of the usual brake-shoe system makes use of the frictional adhesion between the wheels and the track and between the brake shoes and the wheels. Both these quantities vary throughout a considerable range and it is therefore necessary to adjust the pressure between the various members so that it is possible to rely on a definite minimum value.

Adhesion between Wheel Rim and Rails. — The coefficient of adhesion between the wheel rims and rails varies from less than 15 per cent to over 30 per cent depending upon the condition of the track and the relative motion between the track and wheel rim. (*See Railways, Energy Requirements for.*) An adhesion of 15 per cent can usually be depended upon with normal track, and this can be increased to 25 per cent by the use of sand. But these values only obtain while the wheels are rolling on the track. If they begin to slide the coefficient decreases considerably. For this reason the braking effort must always be controlled so that the wheels do not slip.

Adhesion between Brake Shoe and Wheel Rim. — When the brakes are applied, the retarding force is applied below the center of gravity of the car body. The latter is therefore subjected to a couple and tends to press downward at the forward end and upward at the rear end, thus changing the distribution of weight on the axles and decreasing the adhesion on some axles or trucks. It is therefore not possible to figure on using for braking purposes the same weight per axle as exists at standstill. For this reason the brake-shoe adhesion must be less than the track adhesion. The coefficient of adhesion between the customary cast-iron brake shoe and the steel tire of the wheel varies with the speed, and decreases as the time of application increases. As the speed increases the coefficient drops off, being a maximum of from 30 to 25 per cent at speeds from 0 to 5 mi. per hr., 20 per cent at 20 mi. per hr., 14 per cent at 40 mi. per hr., and 7.5 per cent at 60 mi. per hr. Thus at high speeds a heavy pressure may be applied without stopping the wheels, while as the speed of the car diminishes the pressure on the brake shoes must be decreased in order to prevent gripping the wheels and causing them to slide on the track.

Effect of Angular Momentum. — In addition to overcoming the linear momentum of the cars the brakes must overcome the angular momentum of the gears and motor armatures. The effect of the latter is to introduce a tendency of the whole motor to rotate around the car axle and introduce additional strains on the gears and on the trucks. For this reason brake shoes hung between the wheels of a truck are better than those hung on the outside of the wheels.

HAND BRAKES are always provided on cars and locomotives whether power brakes are employed or not, as they are necessary to hold a car left out of service on a grade, because the air brakes will not hold a car standing idle for any

length of time. When a car is descending a very steep grade it is customary to set the hand brakes to hold the speed of the car and reserve the power brakes for emergency or for stopping the car. In hand braking equipment the "foundation" brakes (*see next paragraph*) are actuated through a drum or lever system which is hand operated.

POWER BRAKES. — The "foundation" brakes are that part of the brake equipment usually furnished separately from the power-braking equipment, and consist of the brake shoes, hangers, equalizers, levers, etc., back to the brake cylinder. To this is attached the desired form or make of power brake. Of the various forms of power brakes in use, viz., air, electric, regenerative and electro-pneumatic, the air-brake is the most generally used.

Air-Brakes. — In electric railway practice there are three systems of air-brakes in use, each of which is best suited to a definite type of service and has its particular field, as follows: (1) straight air-brake system for cars always operated singly; (2) emergency straight air-brake system for cars operated in trains of two or three but never more than three cars; (3) automatic air-brake system for cars operated in trains of any number of cars.

Straight Air-brake System. — The equipment for the straight air-brake system consists essentially of a motor-driven compressor, a reservoir, a brake cylinder, a motorman's valve, a train pipe, and the foundation brakes. The brakes are applied by direct pressure, that is by admitting air from the reservoir directly to the cylinder. The advantages of the system are that it is quick-acting and the braking effort is easily controlled to any value desired. Its disadvantage is that in trains a leak in the train pipe renders the brakes ineffective so that there is no means of applying the brakes on the trail-cars if the train should break apart. Sometimes instead of a compressor the motor-car carries a large reservoir which is charged at stations.

Emergency Straight Air-brake System. — This system involves a special valve and an extra pipe on each car so arranged that if the air pressure in the train pipe drops, due to cars breaking apart, this valve automatically turns the pressure of the reservoir into the brake cylinders and applies the brakes. The equipment of the motor car includes an extra pipe and each trail car has a reservoir, two pipes, automatic valve, brake cylinder and foundation brakes. The usual operation in service is like that of the straight air-brake.

Automatic Air-brake System. — This system involves the use of an auxiliary reservoir and a "triple valve" on each car. Whenever the air pressure in the train pipe is reduced, either intentionally or accidentally, this triple valve turns the air pressure of the auxiliary reservoir on each car into the brake cylinders. The brakes are applied by the motorman by opening the service pipe to the air by means of the engineer's valve. The engineer's valve has three positions, "off," "lap," and "on." By turning the handle to the "on" position the train pipe is opened to the atmosphere and the air continuously escapes. This applies the brakes with a continuously increasing pressure. When the desired pressure has been reached the handle is turned to the "lap" position, when the pressure of air in the train pipe and the pressure of the brakes on the wheels remains constant. By turning the handle to the "off" position pressure is restored in the train pipe, the brakes are released, and the reservoirs recharged.

Quick-action Triple Valve. — In any air-brake system an appreciable time elapses between the action of turning the engineer's valve and the actual application of the brakes. If there are many cars in a train the brakes may be applied on the leading cars sometime before they are applied on the rear cars and the result is that the rear cars bump into the forward cars, and may cause a derailment, particularly if this happens on a curve. To guard against this, the

"quick-action triple valve" is used on long trains. This consists of a special form of valve which causes a local intensification of the change in pressure in the train pipe on each car. The action is somewhat similar to a relay which is affected by slight changes in pressure and causes greater changes, and thus applies or releases the brakes more quickly.

Electromagnetic Brakes. — Any braking system making use of the electric current is not as reliable as the air system since if either the trolley comes off or the motors fail to pick up as generators the brakes are inoperative. Electromagnetic braking may be applied either to the axles or directly to the track.

Disc Brakes. — This system comprises two cast-iron discs mounted concentrically on the car axle. One is keyed to the axle and the other anchored to the truck frames. A coil is placed in one of these discs and when a current flows in the coil the two discs are attracted to each other by the magnetism and the friction between them retards the car. The current for the coils may be taken from the trolley or from the motors operating as generators. In the latter case the motors supply an additional retarding force. The braking effort is controlled by resistance in series with the magnet coils.

Track Brakes. — The principle of electromagnetic braking may also be applied to a track brake in which a magnet coil when energized draws a shoe against the rail, the pressure being regulated by a resistance in series with the magnet coil.

Regenerative Braking. — By supplying the field circuits of the motors with a current of proper value and direction by means of separate excitation they may be operated as generators and made to exert a strong retarding effort on the car axles. This separate excitation may be obtained by connecting the field windings of all the motors on a car in series with themselves and with a regulating resistance to the trolley, or by means of a motor generator set (on a locomotive) supplying a low potential of the proper value. The energy developed by the motors when acting as generators may be dissipated in rheostats or may be returned to the distributing system. In the latter case the voltage generated by the motors must be accurately controlled. Ordinarily, if the energy is returned to the line, the braking effort can only be obtained at speeds in the proximity of full speed. Very special means must be provided to make it possible to return energy to the line at low speeds.

Electro-pneumatic Brakes. — This system has been proposed as an improvement over the quick-acting air-brake system. It involves controlling the application of the brakes on each car by means of an electromagnet receiving current from the locomotive cab. By energizing this circuit the motorman can set the air brakes on all cars practically simultaneously. Each car would be equipped with the usual brake cylinders and reservoir and merely the application of the brakes would be controlled electrically.

[W. I. SLICHTER.]

BRAUN TUBE. — (*See also Oscillographs.*) A Braun tube is a special form of vacuum tube with accessory coils or condensers which may be used either for obtaining the shape of an alternating current or voltage wave or for obtaining a diagram the area of which is proportional to the power developed per cycle in an alternating-current circuit. A modification of the tube by Ryan (*see Bibliography*) is particularly well adapted to the measurement of small losses such as occur in the dielectrics of condensers, and small lengths of cables, and for measuring the corona loss (*see article on Corona, Electric*) on short lengths of wires.

CONSTRUCTION OF SIMPLE BRAUN TUBE. — The construction of the tube is illustrated in Fig. 1. It consists of a glass vacuum tube having

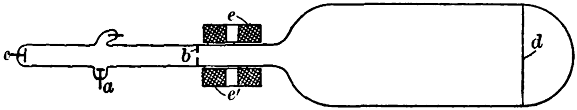

Fig. 1. Simple Braun Tube

electrodes *a* and *c*, a diaphragm *b* with a small hole in it, a thin mica disk *d*, coated with chemicals that fluoresce when struck with cathode rays, and coils *e* and *e'* through which passes the current whose wave shape is to be obtained. With the type of electrode shown in the figure about 20,000 volts between cathode and anode are required to excite the tube. A modified form of electrode, which is maintained at a red heat by an auxiliary current, requires a lower voltage for excitation.

THEORY. — When anode *a* and cathode *c* are connected to a suitable source of *constant* high electromotive force, a stream of cathode particles (electrons) are shot off perpendicularly from the cathode and travel normally in straight lines toward the screen *b*. Only a small pencil of rays passes through the hole in the center of the diaphragm, and this pencil makes a bright spot where it falls on the screen *d*.

The alternating current to be studied is passed through the coils *e* and *e'*, and sets up a magnetic field perpendicular to the stream of cathode particles. This alternating field deflects the ray at each instant by an amount proportional to the instantaneous value of the current, and the spot of light travels back and forth across the screen. By looking at a reflection of the screen in a mirror revolving synchronously with the current through the magnets, the spot of light will appear to trace a wave having the same form as the alternating current which is passed through the coils.

By substituting a revolving film for the revolving mirror and driving the film synchronously with the current through the electromagnets, oscillograms of the alternating currents can be made. The synchronous driving and satisfactory adjustment of mirror or film involve expensive and cumbersome apparatus.

Ryan's Wave Indicator. — To avoid the use of a moving mirror or film Prof. Harris F. Ryan has developed a method whereby the alternating-current wave can be studied directly from the mica screen and a photograph of the screen taken with an ordinary camera. In place of the two coils *e* and *e'* in Fig. 1, four coils at right angles to one another, as shown in sectional view in Fig. 2, are used. The current to be observed is passed through the coils *e* and *e'* and a known sine-wave current is passed through the coils *f* and *f'* at the same time. The spot of light on the screen is then given a motion that is the

resultant of two motions at right angles to each other and proportional to the instantaneous values of their corresponding currents. Owing to the persistence of vision, this results in the production of a closed card upon the screen traced by the spot of light. The wave-form of the current through e and e' may be deduced from an analysis of the photograph or "card."

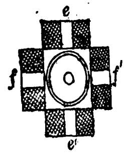

Fig. 2. Sectional View of Coils for Ryan's Wave Indicator

Ryan's Electrostatic Power Indicator. — Professor Ryan has also used the Braun tube as an "electrostatic power diagram indicator," in which the cathode ray is made to trace a diagram that incloses an area proportional to the energy per cycle. For high alternating voltages a condenser is used in place of one set of coils (say ff'); the condenser is so arranged that the electrostatic field, which is proportional to the voltage, deflects the ray in one direction and the magnetic field, which is proportional to the current, deflects it in a direction at right angles to the first deflection.

COSTS. — A Braun-Ryan tube with the accessory coils but without condensers costs about $35.

Chaffee, *A New Method of Impact Excitation of Undamped Oscillations and their Analysis by Means of Braun Tube Oscillographs*, Proc. Am. Ac. Arts & Sciences, 1911, Vol. 47.

[H. Pender and H. R. Ranken.]

BRICKS AND BRICK MASONRY. — (*See also Buildings, Allowable Unit Stresses in; Cement; Concrete.*) Brick construction may be made more ornamental than concrete, but is generally more expensive to place on account of the necessity of handling each brick as an individual unit. The proportion of building and engineering construction in which bricks are used, although still extensive, has been falling off in recent years with the increasing use of plain and reinforced concrete.

Kinds of Bricks. — Ordinary or clay bricks are made by moulding a rectangular block of nearly pure clay, or clay and clean sand, and subsequently burning it in a kiln for from one to two weeks. Sand lime bricks are also used to some extent. They are made from sand cemented by lime and are hardened by being subjected to steam pressure at from 100 to 150 pounds per square inch for about one-half a day. Fire bricks are a special kind of clay bricks, which are made to stand high temperatures. The refractory properties of fire bricks depend chiefly upon the amount of silicon contained. The amount of iron oxide in fire bricks should not exceed 6 per cent. Vitrified bricks are clay bricks which have been annealed by slow cooling.

Physical Properties. — A common, practical test for a good brick is that it will give a clear, ringing sound when struck with a hammer. The color of a brick is not a reliable indication of its strength or properties. The water absorbed in a specified time by a number of bricks is sometimes considered to indicate their relative strengths, as water acts as a lubricant on the material and causes crushing to occur more readily than when dry, but there is considerable difference of opinion as to the value of this test.

The compressive strength of dry bricks ranges from 500 pounds per square inch for soft bricks to over 10,000 pounds per square inch for pressed bricks. The strength of the individual bricks, however, is of little importance except for comparing various kinds, as the strength of brick masonry is usually limited by the strength of the mortar used.

The specific gravity of bricks ranges from 1.6 to 2.6. See also paragraph below on *Brick Masonry* and article on *Weights of Materials*.

Several foreign countries have adopted legal standard sizes for brick, but the only standard sizes in the United States are those specified by the National Brick Mfg. Assoc. as follows:

Common brick...........................	8¼ by 4 by 2¼ inches
Pressed brick...........................	8⅜ by 4 by 2⅜ inches
Paving brick...........................	8½ by 4 by 2½ inches

BRICK MASONRY. — Bricks are laid in lime or cement mortar, the mortar forming a cushion which fills the interstices and keeps out water. Joints, i.e., the spaces between adjacent bricks which are filled with mortar, are usually made from ¼ to ⅜ inch thick in outside walls, and from ⅜ to ½ inch thick in inner walls. In ordinary building work, where the weight of the wall itself is the greater part of the load, lime mortar is usually used because it is cheap. Where strength is required of brickwork, a rich Portland cement mortar should be used; see article on *Cement*. Tests upon the ultimate compressive strength of brick piers are quoted in detail in Johnson's *Materials of Construction*, N. Y., 1910, and Baker's *Masonry Construction*, N. Y., 1910. The values of loads allowed upon brick masonry in various localities range from 100 to 300 pounds per square inch; see *Buildings, Allowable Unit Stresses in*. A brick wall itself weighs from 100 to 145 pounds per cubic foot, depending somewhat upon the quality of the brick and the thickness of joints.

Measurement of Brickwork. — Bricks are usually sold by the thousand. Brickwork is commonly measured by the cubic yard in place, but the units of

per thousand brick and per square yard of surface area are also used. The relation between the number of bricks used and the volume of finished brickwork depends upon the size of brick, thickness of joints and shape of the structure. For solid brick walls the number of bricks per cubic yard ranges from about 400 with ⅝-inch joints to about 500 with ¼-inch joints. An allowance of 3 or 4 per cent excess should be made in estimating to provide for waste and breakage.

Cost of Brickwork.— Hudson River common bricks were quoted at $6.00 per thousand in the *Engineering News*, March 5, 1914. Lime for mortar was quoted at $0.97 to $1.10 per 200-pound barrel. The total cost of brick masonry including labor and materials ranges from $6.00 to $15.00 per cubic yard, depending upon the locality, type of construction and quality of brick and mortar. An average figure for ordinary brick walls is from $8.00 to $10.00 per cubic yard.

[H. F. Thomson.]

BRIDGES FOR ELECTRICAL MEASUREMENTS. — (*See also Inductance and Inductive Reactance; Resistance and Conductance, Electric; Resistors, Standard; Wires and Cables, Insulated.*) Numerous arrangements of electric circuits, known under the general term of "bridges," are used for the comparison of unknown with known resistances, capacities and inductances. The fundamental principle of an electric bridge is the adjustment of the component circuits or arms of the bridge in such a manner that the drop in potential V in the arm formed by the circuit to be tested is to the drop of potential V_r in an arm having known constants as the drop of potential V_a in one "ratio" arm is to the drop V_b in the second "ratio" arm.

A bridge may be made up of separate resistance boxes (*see Resistors, Standard*), but where frequent tests are to be made it is more desirable to have all the resistances, keys, etc., mounted together in a single box. Complete bridges of this kind can be obtained from instrument manufacturers.

SLIDE-WIRE BRIDGE (Fig. 1). — This is the simplest form of bridge but is seldom used in commercial testing, as its range is limited. In principle it is the same as a Wheatstone bridge (*see below*), the difference being a structural one only, in that a wire is used for the "ratio" arms.

The slide wire, AB in Fig. 1, is generally a wire of uniform cross-section stretched along a meter scale which is divided into millimeters. All connections in the X and R circuits are made of heavy low-resistance material. A slider is provided for sliding over and making contact on the wire. When the bridge is balanced (i.e., no current through the galvanometer),

$$X = \frac{AR}{1000 - A},$$

where A is the distance in millimeters between the slider and the left-hand end of the bridge. The slide wire can be made uniform to 1/10 per cent and the error in observation may be even smaller than this. When using a ratio greater than 1 to 1 and when a low resistance is being measured, the errors are greater. It is possible when using an even ratio to make very exact comparisons of the standard and unknown resistances by reversing them and taking the mean of the two measurements.

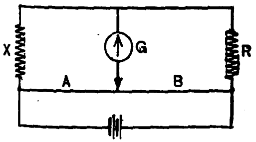

Fig. 1. Slide-wire Bridge

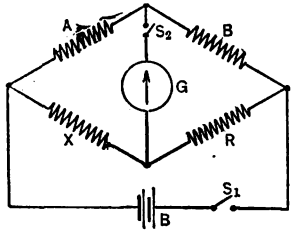

Fig. 2. Wheatstone Bridge

WHEATSTONE BRIDGES. — Fig. 2 shows the arrangement of resistances in the ordinary type of Wheatstone bridge used for comparing resistances. A and B represent two coils or sets of coils, usually referred to as the "ratio" coils, whose relative resistances must be known but whose actual resistance values are unnecessary; R is a standard variable resistance, or resistance box (*see Resistors, Standard*); X is the unknown resistance; G is a sensitive galvanometer connected across two points of the diamond and B is a battery connected across the other two points of the diamond.

For no deflection of the galvanometer when the switches S_1 and S_2 are closed, i.e., when the bridge is balanced,

$$X = \frac{A}{B} \cdot R,$$

where the letters represent the resistances of the four arms.

Construction. — Wheatstone bridges having the various parts mounted in one box may be divided into three classes: (1) portable bridges, in which not only the resistance coils and keys but also the battery and galvanometer are mounted in one box; (2) laboratory bridges, in which the coils and in some cases the keys are mounted in one box, but for which separate galvanometers and batteries must be provided; and (3) precision bridges, arranged in the same manner as laboratory bridges but made with greater care and capable of greater precision.

Since the construction of the resistance coils, blocks, plugs and other minor details of bridges is practically the same as for resistance boxes (*see Resistors, Standard*); only the arrangement of coils and connections will be described here.

Rheostat Arrangements. — The coils forming the rheostat (the variable resistance R in Fig. 2) may be arranged on the 1, 2, 3, 4 plan as shown in Fig. 3, on the 1, 2, 2, 5 plan, on the decade plan of Fig. 4, or on any other plan. (*See Resistors, Standard.*)

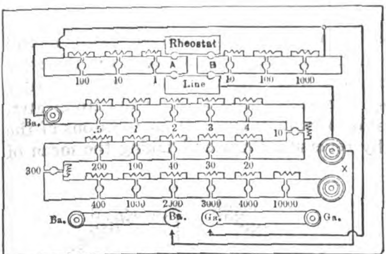

Fig. 3. Wheatstone Bridge (Post Office Type)

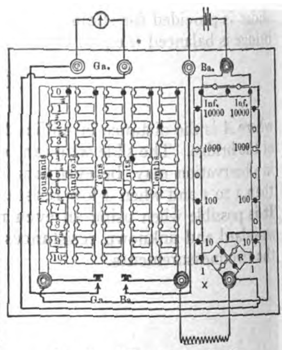

Fig. 4. Wheatstone Bridge (Anthony Type)

The advantage of the decade arrangement is that few plugs are required, and, therefore, there is less likelihood of error due to the contact resistance. A very good form of the decade type of rheostat is used in the Anthony type of Wheatstone bridge, shown in Fig. 4. In this bridge the coils may be joined in series or multiple or in any desired combination of series and multiple.

Plug and Dial Arrangements. — The resistances of the various arms of the bridge may be varied either by the insertion of plugs between the heavy metal terminals of the coils provided on the top of the box, or a dial arrangement similar to that employed on ordinary rheostats (but more carefully made to reduce the contact resistance) may be used.

Ratio Coils (Figs. 5 to 7). — The connections of the ratio arms in a common construction of dial bridge is shown in Fig. 5. The values of the coils are so chosen that the ratio of these coils is always that given by the stamping for various settings of the contact S. An advantage of this type of ratio coils is

that there is no error due to contact resistance in the ratio coils, as the contact is in series with the battery.

The arrangement of an improved form of ratio coils is shown diagrammatically in Fig. 6. This arrangement of ratio coils has the advantage over the old post-office arrangement shown in Fig. 7, in that there are but two plugs to operate and the coils can be checked by reversal.

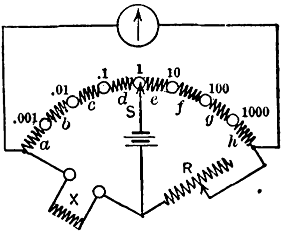

Fig. 5. Dial Type Ratio Coils

Precision of Measurements by Wheatstone Bridge. — The degree of accuracy with which a resistance can be measured by means of a Wheatstone bridge is determined by the following conditions:

1. The accuracy to which the resistances of the various coils is adjusted. The range of accuracy is from about 0.1 per cent for portable bridges to 0.02 per cent for precision bridges.

2. The relative value of the coil resistances and the contact resistances at plugs and terminals. A well-fitting, clean plug has a resistance of from 0.0001 to 0.00005 ohm; a poorly fitting or greasy plug a resistance of 0.01 ohm or higher.

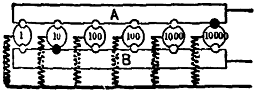

Fig. 6. Improved Arrangement of Ratio Coils

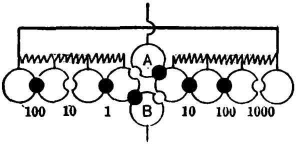

Fig. 7. Post-Office Arrangement of Ratio Coils

The contact resistance at a binding post between the binding post and wire, even when well clamped, ranges from 0.001 to 0.0001 ohm.

3. The relative value of the coil resistances and the insulation resistances between the coils. Dirt and grease on the top of the box may introduce a considerable error. Hard rubber, which is commonly used for the tops of resistance boxes, is also liable to have a thin film of acid formed on it when exposed for a long period to the action of the moisture and impurities in the air, which attack the sulphur in the rubber. Such a film will greatly reduce the insulation resistance between the lugs on top of the box.

4. The effect of changes of temperature in changing the resistances of the coils and in producing thermoelectric effects. The thermal e.m.f. in a copper-brass-copper circuit is about 2×10^{-6} volts per degree C. difference in temperature between the two junctions. Thermoelectric troubles can usually be avoided by reversing the connections of the battery to the bridge and taking the mean of the values of the resistances corresponding to the balance when the battery current flows through the bridge first in one direction and then in the other.

5. The maximum current that the coils will safely carry; this ranges from about 0.5 ampere for 1-ohm coils down to 0.005 ampere for a 5000-ohm coil.

6. The resistances of the galvanometer and battery, particularly the former. The battery resistance is usually small.

7. The relative resistances of the various arms of the bridge.

8. The sensitiveness of the galvanometer, i.e., the deflection per unit current.

Best Galvanometer Resistance. — Referring to Fig. 2, the best galvanometer resistance is

$$G = \frac{(A + X)(B + R)}{A + B + R + X},$$

where the letters designate the resistances of the various branches.

Best Location of Galvanometer. — Knowing the galvanometer and battery resistances (the galvanometer resistance is usually the larger), connect the one having the higher resistance so that it joins the junction of the two arms of the bridge having the highest resistances to the junction of the two arms having the lowest resistances.

Precautions in Making Measurements. — The following rules should be observed in using a Wheatstone bridge:

1. Do not employ a battery having an e.m.f. of over 5 volts; a lower value is desirable if sufficient sensitiveness can be obtained.
2. Always shunt the galvanometer during preliminary adjustments. The shunt circuit should be opened when the final balance is made.
3. See that all binding posts are screwed up tightly and all plugs firmly inserted. After withdrawing a plug those adjacent to it should be retightened.
4. For a preliminary balance use a 1 to 1 ratio.
5. In manipulating the keys be careful not to touch the metal work, as the heat and moisture of the hand is likely to set up appreciable electromotive forces.
6. Always close the battery switch first and then the galvanometer switch, to avoid momentary deflections of the galvanometer due to the transient e.m.f.'s set up while the currents are establishing themselves.
7. If the contact or lead resistances are appreciable relative to the resistances of the coils with which they are in series, these resistances should be separately determined.

Care of Bridge. — In order that a bridge or resistance box may remain in first-class condition, it must be carefully protected from dust and moisture by being covered when it is not in use. To insure high insulation the top must be kept clean, especially between the blocks. The plugs must be kept free from grit, grease or from contact with mercury. Grease may be removed by the use of a little benzol. Never use sand or emery paper for cleaning the plugs or holes, for the surfaces of the taper will be spoiled by this treatment. These materials work into the metal and cannot be removed, thus causing the plugs to "cut." If it becomes absolutely necessary to clean the plugs and sockets, a little of the very finest whiting may be employed. Extra holes of the proper taper bored in the brass blocks are convenient for holding the plugs when they are not in use, and also for attaching a movable terminal. Never apply undue force in inserting the plugs. (*From Laboratory Notes by Prof. F. A. Laws.*)

KELVIN BRIDGE. — The ordinary form of Wheatstone bridge is not suitable for measuring with accuracy a resistance of 0.1 ohm or less, due to the contact resistances introduced at the binding posts, this contact resistance being of the order of 0.0001 to 0.001 ohm. An arrangement of circuits to avoid these contact resistances devised by Lord Kelvin (*Wm. Thomson*) is shown in Fig. 8, and is known as the Kelvin or Thomson bridge. There will be no current in the galvanometer when

$$X = \frac{A}{B} \cdot R + \frac{bd}{a + b + d}\left(\frac{A}{B} - \frac{a}{b}\right).$$

If $\frac{a}{b}$ is made equal to $\frac{A}{B}$, then

$$X = \frac{A}{B} \cdot R.$$

It is also well to make the resistance of d extremely low in comparison with X or R since the lower the resistance of d the less an error in $\frac{a}{b} = \frac{A}{B}$ will affect the accuracy of measurement.

In the above formulas X and R are the resistances between the arrowheads, which represent the "potential terminals." Such terminals are always provided on low-resistance standards (*see Resistors, Standard*).

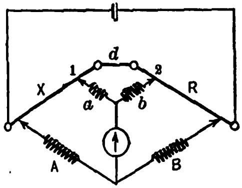

Fig. 8. Kelvin Bridge

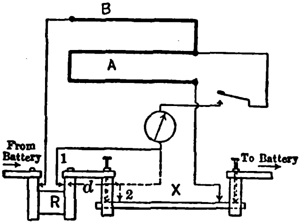

Fig. 9. Modification of the Kelvin Bridge

Simple Modification of the Kelvin Bridge. — When suitable resistances are not available for a and b, these resistances may be omitted and the galvanometer terminal be connected first at 1 and then at 2, and A adjusted for a balance in each case; let A_1 and A_2 be the corresponding values of A. Then

$$X = R\frac{A_1(B + A_2)}{B(B + A_1)}.$$

This method is very convenient for measuring the resistance X of a low-resistance shunt (*see Shunts*). The only standard resistances required are a low-resistance standard R and a resistance box with three terminals (or two separate resistance boxes). Fig. 9 shows such an arrangement.

HOOPES' CONDUCTIVITY BRIDGE. — This bridge is also a modification of the Kelvin bridge, designed for the rapid determination of the relative conductivity (*see Resistance and Conductance*) of samples of wire. It is extensively used in wire factories.

A diagram of the connections is shown in Fig. 10.

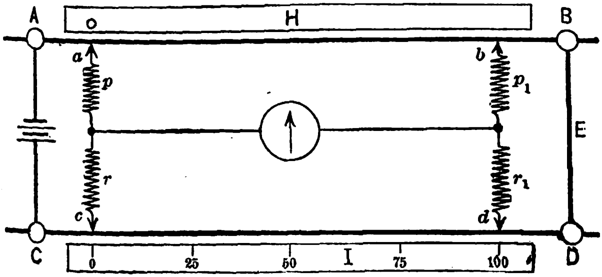

Fig. 10. Hoopes' Conductivity Bridge

The standard A–B and the unknown C–D are of the same metal; consequently if care be taken that they are at the same temperature, all corrections due to temperature are avoided. The arms p, r, p_1, r_1 are in the same case and are

made of material of low-temperature coefficient so that their relative values will not change. They are adjusted so that $p = r$ and $p_1 = r_1$; consequently at balance the resistance of $C-D$ equals the resistance of $A-B$.

The sample $C-D$ is placed alongside a scale I divided into 100 parts, so that the graduations represent percentages of the total length of the scale. Accompanying the standard wire $A-B$ is a scale H, on which are laid off a number of points corresponding to the weights of the standard length (38 inches) of a range of sizes of sample wires.

To make a conductivity reading, the weight of the standard length of the sample $C-D$ is found to within an accuracy of 1/20 per cent. The contact b is set at the point on scale H corresponding to this weight, the contacts a and c being at the zero points of their respective scales. After the case has been closed a sufficient length of time to allow both the standard and sample to assume the same temperature, the contact d is moved until the galvanometer shows no deflection; this will occur when the resistance between a and b is equal to that between c and d. The scale reading corresponding to the position of d for a balance is equal to the per cent conductivity.

The Hoopes' bridge is so designed that the standard wire with its scale is removable from the bridge and so that a single standard covers a range of sizes equal to 3 numbers of B. & S. gauge. Any number of standards can be supplied with a bridge, so that it can cover an extensive range of sizes and can also be used for wires of different materials. In order to keep the standard wire and the test wire at the same temperature the bridge is mounted in a metal-lined case and the scale read through a glass window in the case, the window being closed by a metal screen when readings are not being taken.

COSTS. — A good slide-wire bridge costs about \$20, a portable Wheatstone bridge from \$50 to \$125, depending upon the design, a laboratory Wheatstone bridge from \$25 to \$75 and a high-precision standard bridge from \$200 to \$400. A Hoopes' conductivity bridge with a single standard, covering 3 sizes of B. & S. gauge wire, costs about \$500; additional standards cost about \$50.

[C. M. SPOFFORD.]

BUS-BARS AND BUS-BAR STRUCTURES. — (*See also Circuit Breakers; Power Stations; Substations; Switches; Switchgear Equipment for Power Stations; Wires and Cables.*) Bus-bars, or "omnibus bars," as they were originally called, are the common circuits into which the various generators deliver their output and from which the different feeders draw their supply of power. In large-capacity, moderate-voltage a-c. plants the bus-bars are usually placed in structures and connected to the various generators, feeders, etc., by suitable wiring. The bus-bars and their connections, together with the bus-bar structures, form one of the most important parts of large plants, as the entire energy of the station is usually concentrated thereon.

BUS-BAR SYSTEMS. — Where there is only a single set of bus-bars either in d-c. or a-c. stations the connections are said to be arranged on the "single-throw" system; when the connections can be made to either of two sets of bus-bars the system is spoken of as "double-throw"; but if the connections can be made to both sets of bus-bars instead of only to either set, the system is spoken of as the "selector system." Occasionally three or more sets of bus-bars are used.

If there is only one set of bus-bars, but with switches provided for dividing it into one or more sections, it is spoken of as a "sectioned bus." Where there are two sets of these sectioned bus-bars connected together at the ends, the system forms a "ring bus." In many high-voltage plants having step-up transformers each generator normally connects to the low-tension side of its own transformer but switches are provided so that any transformer or generator can connect to a bus; such a bus is spoken of as a "relay bus." Where a number of feeders connect to a bus which in turn connects to the main bus through a switch or breaker, such a bus is spoken of as a "group bus."

Uses of Various Systems. — The various systems — single bus, double bus, relay bus, group bus, etc., — all have their advantages and disadvantages. The single bus is naturally the cheapest, simplest and least flexible, and trouble on the bus is apt to shut down the plant. The other systems are more flexible and also more expensive as they require more apparatus. In every installation a compromise must be effected between cost and flexibility, and each case must be considered on its own merits. In small low-voltage plants bus-bar trouble is almost unknown and a single-throw system is usually employed. In high-voltage, large-capacity plants, although bus-bar trouble is rare, a more flexible system than the single-throw is often advisable.

BUS-BAR MATERIAL. — Depending on the current and voltage, bus-bars may be made of wire, rod, tubing, cable or strap, either bare or insulated. Solid wire is seldom used for more than 200 amperes, rod is used for less than 1000 amperes, tubing for 300 to 600 amperes, cable up to 1000 amperes, while strap is used up to any capacity.

Strap Bars for Heavy Currents. — Strap for bus-bars, particularly for heavy currents, possesses several advantages over other shapes, the chief ones being the ease with which additional straps may be added and the excellent radiating surface secured. Straps are made in various sections, a typical one being 3 inches by 1/8 inch. Where more than one strap is required a space of 1/8 inch is kept between bars, making the so-called laminated bus. The connections from switches, circuit breakers, etc., to the bus are made of one or more similar straps suitably interleaved and clamped together. For very heavy currents straps of larger section are used.

Tubing for Small Currents and High Voltages. — For extremely high voltages with their correspondingly small current, copper tubing for bus-bars and

connections has many advantages over rods, wire or strap. These advantages are principally increased stiffness for the same amount of material, large and effective radiating surface, and the facility of making connections by flattening out the tubing at the point desired and bolting the tubing together at such points. On extremely high-voltage circuits tubing of approximately 1 inch outside diameter is not apt to be troubled by the brush discharge or corona effect that is sometimes noted with small wires or straps having sharp edges. In some plants iron piping is used for bus-bars and connections.

BUS-BAR STRUCTURES. — (*See also Power Stations; Substations; Switchgear.*) In large-capacity a-c. plants of 13,000 volts or less, with generators connected directly to the bus, the current that can be developed on a short-circuit is something enormous, and every precaution has to be taken to prevent trouble from spreading if it ever starts. For this reason it has become customary to employ masonry compartments and cellular construction for the oil circuit breakers and bus-bars. In higher-voltage plants open wiring possesses several decided advantages. The vertical walls and septums of the circuit-breaker and bus-bar structures are usually built of brick or concrete, and the horizontal shelves between the bus-bars are ordinarily made of concrete, sandstone, soapstone, slate or marble. These substances are named in the order of their increasing cost. In some instances the bus-bar structures have been made of asbestos lumber, transite or similar material.

Marble is undoubtedly the best material as far as insulation and absorption qualities go, but its high cost and its liability to crumble when exposed to a bad arc has caused the adoption of cheaper materials of slightly poorer insulating qualities. Slate, the next material tried, is a very uncertain insulator for high-voltage work and it has been generally superseded by soapstone, sandstone or concrete. Where space is at a premium, soapstone is used almost exclusively, as it can be drilled, machined, etc., and smaller clearance distances can be used than would be permissible with sandstone or concrete. Where there is a chance to secure a reasonable distance between bare metal parts and the shelves or barriers, concrete, either plain or reinforced, can be used to advantage.

Supports for Bus-Bars. — Low-tension bus-bars, when not too heavy, can be supported by the wall bushing for the lead. For heavier work, or where bushings are not used, the bus-bars are supported on porcelain pillars, petticoat insulators or similar devices resting on the bus-bar shelf or attached to the wall.

For supports for high-tension bus-bars and connections it is customary to employ line insulators either of the pillar type, pin type, or suspension type, depending on the voltage.

OPEN WIRING FOR BUS-BARS. — Some engineers are of the opinion that the cellular construction should be used for large-capacity circuits of any voltage, and bottom-connected breakers have been designed that work well with the inclosed bus-bar construction for high-voltage plants.

The writer is of the opinion that the open system of wiring is preferable for any voltage higher than that for which generators can be conveniently wound. This opinion is based on the following reasons:

1. For the same kilovolt-ampere capacity back of an arc the current established is approximately inversely proportional to the voltage, and consequently the violence of the arc and its destructive effects are less on a high-voltage than on a low-voltage system.

2. The distance from wire to ground has to be greatly reduced from what could be obtained with open wiring in the same space, as the conductivity of the

fireproof barriers is sufficiently good to permit large currents to flow with high voltages, in case an arc or a dead ground is established.

3. A more expensive building and more costly construction are usually needed for inclosed bus-bars and wiring than are required for open wiring.

4. Inspection and repairs are more difficult when bus-bars, wiring, disconnecting switches and similar appliances are boxed in masonry compartments, and the conductors are visible and accessible only by the removal of doors. Inspection will be more frequent and thorough and incipient trouble will be noticed far sooner with open wiring than with inclosed, as the station attendant can see everything in a walk of a few minutes, and will not have to remove many doors and visit two or three floors to examine the condition of the apparatus.

CONNECTIONS TO BUS-BARS. — Where the currents exceed 600 or 800 amperes, it is usual to employ laminated copper straps for connecting to bus-bars; for smaller currents, cable, wire, rod or tubing is used. Cable and, to a certain extent, bare wire are used for connections involving bends or long runs through conduits, but for straight runs or simple bends rod or tubing can be used. Tubing, though more costly than rod or wire, is stiffer for the same section, and can often be flattened out for making connections to studs, bars, etc., without the necessity of additional terminals.

[S. Q. Hayes.]

CALORIMETERS, FUEL. — (*See also Fuel.*) A fuel calorimeter is an instrument for determining the heating value of a fuel. Its essential features are a closed chamber in which a weighed sample of the fuel can be quickly and completely burned, a vessel of water surrounding this chamber, into which all the heat generated by the combustion is transferred, a delicate thermometer for measuring the rise of temperature of the water, means for igniting the fuel, and provisions for preventing loss of heat from the apparatus by radiation or by the escape of the gases and vapors produced by the combustion. The most approved form of the instrument is Mahler's modification of Berthelot's calorimeter. The combustion chamber is a strong cylindrical steel vessel enameled on the inside, called a "bomb," into which about 1 gram of powdered coal, contained in a small platinum dish, is placed. Oxygen under pressure of 20 to 25 atmospheres is introduced, and the coal is ignited by an electric spark and burned explosively. The bomb is set in a water pail of thin brass, which is heavily felted and surrounded by a double-walled vessel filled with water of the temperature of the room. A stirring apparatus is used in the pail to circulate the water around the bomb. The thermometer is finely graduated. Readings of the temperature are made and recorded every minute until the maximum is reached, and a few minutes afterward to obtain a correction for radiation. The weight of the water, together with the water equivalent of the bomb and pail, multiplied by the rise in temperature, corrected for radiation and other minor errors, gives the number of heat units generated by the combustion of the coal.

The Junker calorimeter is commonly used to determine the heating value of fuel gas. A measured volume of gas is burned with air or oxygen in a vessel which is surrounded with water, and the calculations are made in the same way as those for the Mahler calorimeter.

[WM. KENT.]

CALORIMETERS, STEAM. — (*See also Steam.*) For the purpose of determining the percentage of moisture in the steam, in a boiler or engine test, a steam calorimeter is used. Several forms of this instrument have been used but the most common is that of Professor Peabody, known as the throttling calorimeter. The action of this instrument depends upon the fact that the heat of saturated steam is greater the greater the pressure, and consequently if the pressure is reduced by throttling, the heat rendered available will convert the moisture into steam and in general produce more or less superheating.

A ½-inch pipe, closed at the end and perforated with several ⅛-inch holes in its walls, is inserted into the main steam pipe so that steam may enter these holes. The other end of the calorimeter pipe is throttled by an orifice 1/16 inch diameter through which the steam escapes into a chamber which has an outlet to the atmosphere. The temperature and pressure of the steam on each side of the orifice are observed. The steam in the chamber is superheated more or less, according to the amount of moisture contained in the sample drawn from the steam main.

The per cent of moisture in the steam is then

$$W = 100 \frac{H - h - K(T - t)}{L},$$

where H = total heat and L = the latent heat of saturated steam at the pressure of the steam in the main pipe; h = total heat of saturated steam at the pressure in the discharge chamber of the calorimeter (= 1150.4, corresponding to a pressure of 14.7, when this chamber opens directly to the atmosphere); K = specific heat of superheated steam (= 0.48 approximately); T = actual temperature in the discharge chamber; t = temperature of saturated steam at the pressure in the discharge chamber (= 212 when this chamber opens directly to the atmosphere). The above formula becomes

$$W = 100 \frac{H - 1150.4 - 0.48(T - 212)}{L},$$

when the discharge chamber opens directly to the atmosphere, and when the atmospheric pressure is 14.7 pounds per square inch.

When the steam is very moist, so as to reduce the superheating on the discharge side to 0°, the instrument fails, and a separating calorimeter, which is simply a small steam separator (q.v.), must be used between the throttling calorimeter and the steam pipe to collect the greater quantity of moisture. The moisture collected in the separator is then added to that determined by the calorimeter. The instrument must be thoroughly felted to reduce the error due to radiation. There is also usually a considerable error in obtaining steam of an average quality from the main pipe by the perforated tube.

BIBLIOGRAPHY. — Carpenter and Diederichs, *Experimental Engineering*, N. Y.; *Report of Committee on Power Tests, A.S.M.E.*, 1912; *various papers in Trans. A.S.M.E*, 1884, 1889, 1890, 1891 (Vol. 6, 10, 11, 12).

[Wm. Kent.]

CAMBRIC, VARNISHED. — (*See also Insulating Materials; Wires and Cables, Insulated.*) Varnished muslin, variously known as varnished cloth or varnished cambric, is an insulating material which is superseding both rubber (q.v.) and impregnated paper (q.v.) for many purposes. It consists of strips of cotton fabric coated with insulating varnish, wound helically around the conductor with a thin layer of plastic non-hardening compound between turns. This compound prevents the absorption of moisture, precludes air spaces and permits the layers of fabric to slide upon each other when the cable is bent.

The muslin is prepared by coating it with a mixture whose principal constituents are boiled linseed oil, resin and benzine. This mixture dries and the oil oxidizes in contact with the air leaving a hard smooth surface. Several coats are thus applied until the desired thickness is obtained. The plastic material between layers is a mixture of petrolatum or crude vaseline and resin. Different manufacturers use other constituents, with considerable improvement in the quality of the insulation. The exact nature of the impregnating compounds is kept secret.

SPECIFIC RESISTANCE. — The value of K in the formula $M = K \log \frac{D}{d}$ (*see article on Rubber*) ranges from $K = 500$ to $K = 4000$, the usual figure being between 700 and 1200, and anything over 2000 exceptional.

Temperature Coefficient of Resistance. — The resistance of varnished cloth is more affected by temperature changes than that of rubber or impregnated paper. The amount of variation differs in different makes, so that the accompanying table should be considered as an approximation only.

Temperature, ° F.	Per cent of resistance at 60° F.
60	100
65	61.4
70	36.8
75	23.8
80	14.9
85	10.5
90	7.90
95	6.14
100	5.26

DIELECTRIC STRENGTH. — The varnished fabric is usually 12 or 15 mils thick, and will stand a puncture test of about one kilovolt for five minutes. A 250,000 circular mil cable, insulated with 3/8 inch of varnished cambric, when subjected to a gradually increasing potential, punctured at 115 to 118 kilovolts. A well-designed varnished cloth cable can be subjected to a one-half hour test of double the working voltage and to an instantaneous voltage of three times the working voltage. Varnished-cloth cables seem to have the property of withstanding comparatively high instantaneous rises of voltage such as occur at the time of surges (*see Transmission Lines*), and hence there is no necessity of subjecting them to prolonged tests of two and one-half or three times the working voltages, which have a tendency to overheat the insulation. (*H. W. Fisher.*)

SPECIFIC INDUCTIVE CAPACITY. — Varnished cloth is made with specific inductive capacities from 4 to 6. The former figure is only occasionally attained, the average being about 5. A maximum of 6 may be relied upon, as it allows a slight margin over the ordinary variations of manufacture.

SPECIFICATIONS. — See article on *Wires and Cables, Insulated.*

CAPACITY AND CHARGING CURRENTS. — (*See also Alternating Currents; Condensers, Electric; Insulating Materials, Testing of; Transient Electric Phenomena and Oscillations; Transmission Lines; Wires and Cables, Insulated.*) In the section on *Capacity and Condensers*, in the article on *Electricity and Magnetism, Principles of*, are given the formulas for capacities in series and in parallel and for the energy stored in a charged condenser. For units and their interrelations see the articles *Units, Practical Electrical*, and *Units and Conversion Factors*. Commercial forms of condensers are described in the article on *Condensers, Electric*. The following is a brief table of contents of this article.

GENERAL RELATIONS AND DEFINITIONS. — Consider any number of conductors 0, 1, 2, 3, etc., either (1) at a great distance from all other conductors or (2) completely surrounded by a hollow conducting shell, the inside surface of which shell is to be considered as one of the conductors, say No. 0, of the system. The electrostatic condition of such a system of conductors is uninfluenced by any electrostatic effects produced outside the system; it may therefore be called an "electrostatically independent system."

Potential Coefficients (A). — Any conductor of an electrostatically independent system may be chosen as a conductor of reference; let this reference conductor be designated as conductor No. 0. Let v_{10}, v_{20}, v_{30}, etc., represent the potential drop from No. 1 to No. 0, from No. 2 to No. 0, from No. 3 to No. 0, etc., and let q_0, q_1, q_2, q_3, etc., represent the charges on No. 0, No. 1, No. 2, No. 3, etc. Then, if the relative positions of the various conductors and insulators in the field remain unaltered and the specific inductive capacities (*see Electricity and Magnetism, Principles of*) of the various insulating materials between the conductors are *constant* (not necessarily the same for each insulating material, however), the following relations hold for all values of the charges on and potential drops between conductors irrespective of how the conductors may be connected: *

$$\left.\begin{aligned} v_{10} &= A_{11}q_1 + A_{12}q_2 + A_{13}q_3 + \text{etc.}, \\ v_{20} &= A_{12}q_1 + A_{22}q_2 + A_{23}q_3 + \text{etc.}, \\ v_{30} &= A_{13}q_1 + A_{23}q_2 + A_{33}q_3 + \text{etc.}, \\ q_0 &= -(q_1 + q_2 + q_3 + \text{etc.}), \end{aligned}\right\} \tag{1}$$

where the A's are all *constants* depending upon the distances apart of the con-

* By wires of small cross-section and length compared with the dimensions of the conductors.

ductors and the nature of the insulating medium between them. The coefficients A in these equations may be called the "potential coefficients" of the system of conductors. It should be noted particularly that *these coefficients are independent of how the conductors may be charged and of how they may be interconnected* (provided the connecting wires are small compared with surfaces of the conductors). In certain simple cases these coefficients A are readily calculated; see below.

Electrostatic Induction Coefficients (B). — The above equations may also be written

$$\left.\begin{aligned} q_1 &= B_{11}v_{10} + B_{12}v_{20} + B_{13}v_{30} + \text{etc.}, \\ q_2 &= B_{12}v_{10} + B_{22}v_{20} + B_{23}v_{30} + \text{etc.}, \\ q_3 &= B_{13}v_{10} + B_{23}v_{20} + B_{33}v_{30} + \text{etc.}, \end{aligned}\right\} \qquad (2)$$

etc.

$$q_0 = -(q_1 + q_2 + q_3 + \text{etc.}),$$

where the B's are also constants and may be expressed directly in terms of the potential coefficients A by solving equations (1) for q_1, q_2, q_3, etc. The constants B are called the "electrostatic induction coefficients," and like the constants A are independent of how the conductors may be charged and of how they may be interconnected. The B's may be expressed directly in terms of the normal and grounded capacities of the various conductors; see below.

Normal Capacity of Two Conductors (C). — By the normal capacity between any two conductors is meant the capacity of the condenser formed by these two conductors when all the other conductors are connected to one another and to the conductor of reference. The normal capacity between any two conductors of a system, say Nos. 1 and 2, is, then, from equation (2),

$$C_{12} = \frac{B_{11}B_{22} - B_{12}^2}{B_{11} + B_{22} + 2\,B_{12}}. \qquad (2a)$$

When the arrangement of the conductors is perfectly symmetrical (as in a three-conductor cable), $B_{11} = B_{22}$ and the normal capacity between 1 and 2 is

$$C_{12} = \frac{1}{2}(B_{11} - B_{12}). \qquad (2b)$$

Grounded Capacity (C_g). — By the grounded capacity of any conductor of a system is meant the capacity of the condenser formed by this conductor as one "plate" and all the other conductors, including the conductor of reference, connected together as the other plate.* The grounded capacity of conductor No. 1, say, is then, from equation (2),

$$C_{1g} = B_{11}. \qquad (2c)$$

That is, the "electrostatic coefficient of self-induction" of any given conductor is the same as the grounded capacity of this conductor.

Capacity to Neutral (C_0). — In calculating the charging current, voltage drops, etc., in a single-phase or balanced three-phase transmission line it is sometimes convenient to consider the actual capacity between wires as made up of two capacities in series, each of twice the actual capacity between wires. This double capacity, viz.,

$$C_0 = 2\,C_{12}, \qquad (2d)$$

is called the capacity to neutral, since this capacity multiplied by the voltage to neutral, in either a single-phase or balanced three-phase line, gives the charge per wire, which charge is also in phase with the voltage to neutral. This prod-

* The term "grounded" arises from the fact that the conductor of reference is usually the ground.

uct, however, does not give the charge per wire when the system is unbalanced; the general equations (2) must then be used.

Charging Current and Capacity Susceptance. — The charging currents taken by the various conductors of a system are found by differentiating equations (2) with respect to time; this gives the instantaneous values of the charging currents. In the case of sine-wave voltages all of frequency f, the effective values and phase relations of the charging currents in each conductor, in terms of the voltage drops to the conductor of reference, *all expressed in vector notation* (*see Alternating Currents*), are as follows:

$$\left.\begin{aligned} I_1 &= j\,2\pi f\,(B_{11}V_{10} + B_{12}V_{20} + B_{13}V_{30} + \ldots\ldots\ldots\ldots\ldots) \\ I_2 &= j\,2\pi f\,(B_{12}V_{10} + B_{22}V_{20} + B_{23}V_{30} + \ldots\ldots\ldots\ldots\ldots) \\ I_3 &= j\,2\pi f\,(B_{13}V_{10} + B_{23}V_{20} + B_{33}V_{30} + \ldots\ldots\ldots\ldots\ldots) \\ &\text{etc.,} \\ I_0 &= -\,(I_1 + I_2 + I_3 + \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots) \end{aligned}\right\} \quad (3)$$

Note that the quantities in the brackets are to be added *vectorially*.

In the case of a system of but two conductors, i.e., a simple condenser, these relations reduce to

$$I = j\,2\pi fCV, \quad (3a)$$

when V is the voltage drop through the condenser, I the current in the direction of this drop, and C the capacity of the condenser. That is, the charging current of a simple condenser leads the voltage drop by 90° and is equal numerically to the product of this voltage by $2\pi fC$. The factor

$$b = 2\pi fC \quad (3b)$$

is called the capacity susceptance * of the condenser. Capacity susceptance is expressed in mhos or micromhos, being of the same dimensions as conductance. Numerically, the charging current of a simple condenser may be then expressed as

$$I = bV. \quad (3c)$$

When V is in volts and b in mhos, the current I is in amperes: For either a single-phase or balanced three-phase line the charging current per wire may also be expressed as $I = b_0V_0$, where $b_0 = 2\pi fC_0 = 2\,b$, and may be called the "capacity susceptance to neutral." When b_0 is in micromhos (see tables below) and V_0 is in volts to neutral, the charging current per wire is

$$I = 10^{-6}b_0V_0. \quad (3d)$$

In a single-phase line $V_0 = V/2$ and in a balanced three-phase line $V_0 = V/\sqrt{3}$, when V in each case is the voltage between wires.

FORMULAS FOR THE CAPACITY OF SIMPLE CONDENSERS. — Let

K = specific inductive capacity of medium between conductors; medium assumed uniform; for air $K = 1$,
C = capacity of the condenser formed by the two conductors,
$C_0 = 2\,C$ = capacity to neutral.

Two Concentric Spheres. — Let r' = internal radius of outer sphere and r = external radius of inner sphere, both in centimeters, and R' and R the corresponding dimensions in inches.

$$C = \frac{Krr'}{r' - r} \quad \text{statfarads,}$$

$$= 2.822 \times 10^{-6}\frac{KRR'}{R' - R} \quad \text{microfarads.}$$

* The inductive susceptance of a condenser is $-2\pi fC$; see *Alternating Currents*.

Two Parallel Plates. — Unless the plates are large compared with their distance apart no simple formula can be deduced, since the electrostatic field at the edge of the plates is not uniform. Let $S =$ surface, in square inches, of contact between the metal plate and dielectric (the dielectric sheet is usually larger than the metal sheet, hence S is generally the surface, one side only, of the metal plate); $D =$ thickness of dielectric in inches, $K =$ specific inductive capacity, and let s and d be the dimensions in centimeters corresponding to S and D respectively. Then for D small compared with S, the capacity of two parallel plates is

$$C = \frac{Ks}{4\pi d} \quad \text{statfarads}$$
$$= 2.246 \times 10^{-7} \frac{KS}{D} \quad \text{microfarads.}$$

Stack of Plates. — Let $N =$ the number of *metal* plates in the stack; there will then be $N - 1$ effective dielectric sheets or $N - 1$ parallel plate condensers in series. Using the same notation as above, the capacity of a stack of N metal plates, *connected in series*, is

$$C = \frac{Ks}{4\pi d\,(N-1)} \quad \text{statfarads}$$
$$= 2.246 \times 10^{-7} \frac{KS}{D\,(N-1)} \quad \text{microfarads.}$$

Round Wire in Concentric* Sheath. — Dimensions as in Fig. 1; since the *ratio* only is involved, it is immaterial what units are used for D and d provided *both* are expressed in the *same* unit. For a length of cable long compared with its diameter,

$$C = \frac{K}{2 \log_\epsilon \frac{D}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{7.354 \times 10^{-3} K}{\log_{10} \frac{D}{d}} \quad \text{microfarads per 1000 ft.}$$

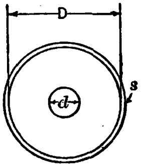

Fig. 1.

Two Parallel Round† Wires. — Dimensions as in Fig. 2; since the *ratio* only is involved, it is immaterial what units are used for D and d provided *both* are expressed in the *same* unit. For a length of line large compared with the distance apart of the wires, the exact formula ‡ for the capacity *between wires* is

Fig. 2.

* When the wire is off center by a distance m (center of wire to center of sheath),

$$C = \frac{K}{2 \cosh^{-1}\alpha} \quad \text{statfarads per centimeter}$$

$$= \frac{16.93 \times 10^{-3} K}{\cosh^{-1}\alpha} \quad \text{microfarads per 1000 ft.,}$$

where $$\alpha = \frac{D^2 + d^2 - 4\,m^2}{2\,Dd}.$$

† When the wires are far apart compared with the linear dimensions of their cross-section, the second group of formulas also applies approximately to wires of any shape of cross-section provided d is taken equal to the perimeter of the cross-section divided by π, i.e., equal to the "equivalent" diameter of the cross-section.

‡ Taking into account the non-uniform distribution of the charge on each wire; see *Pender and Osborne, Elec. World, 1910, Vol. 56, p. 667.*

$$C = \frac{K}{4 \cosh^{-1} \dfrac{D}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{8.467 \times 10^{-3} K}{\cosh^{-1} \dfrac{D}{d}} \quad \text{microfarads per 1000 feet.}$$

When D is greater than 10 d the following formulas for the capacity *between wires* may be used instead of the above with an error of less than 0.1 per cent:

$$\left.\begin{aligned} C &= \frac{K}{4 \log_{\epsilon} \dfrac{2D}{d}} && \text{statfarads per centimeter} \\ &= \frac{3.677 \times 10^{-3} K}{\log_{10} \dfrac{2D}{d}} && \text{microfarads per 1000 feet} \\ &= \frac{19.41 \times 10^{-3} K}{\log_{10} \dfrac{2D}{d}} && \text{microfarads per mile.} \end{aligned}\right\} \quad (4)$$

The *capacity to neutral* in all cases is $C_0 = 2\,C$. Tables of capacity to neutral for various sizes of wires and various spacings, when separated by air ($K = 1$), are given in the tables below. Note that these tables and the above formulas are strictly applicable to ordinary overhead lines only when the distance from the wires to other conductors, particularly the earth, is large compared with their distance apart. However, the effect of the earth is usually small in most practical cases (see below), and the formulas and tables give a very fair approximation to the actual capacities.

The capacities of standard strands given in the following tables are calculated by the same formula as for smooth round wires using for the diameter d the diameter of the strand; see *Wires and Cables, Bare*. The values as thus calculated are therefore not exact, but the error is probably less than 3 per cent for all practical cases.

CAPACITY TO NEUTRAL* OF SMOOTH ROUND WIRES

Microfarads per 1000 FEET of each wire of a single-phase or of a symmetrical three-phase line

* The susceptance *between* conductors equals one-half the values given in this table.

Single Round* Wire Parallel to the Ground. — Dimensions as in Fig. 3. The dotted circle represents the "image" of the wire in the plane. The capacity of the actual condenser formed by the wire and the earth (assumed equivalent to an infinite conducting plane parallel to the wire) is the same as the capacity to neutral of the fictitious condenser formed by the wire and its image, the distance between the two wires of this fictitious condenser being $D = 2H$. Hence using the approximate expressions, since the wire is practically always more than 10 times its diameter above the other, the capacity *between the wire and the earth* is

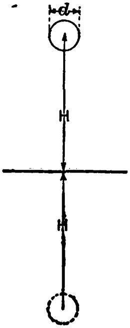

Fig. 3.

$$C = \frac{K}{2\log_e \frac{4H}{d}} \quad \text{statfarads per centimeter}$$

$$= \frac{7.354 \times 10^{-3} K}{\log_{10} \frac{4H}{d}} \quad \text{microfarads per 1000 feet}$$

$$= \frac{38.83 \times 10^{-3} K}{\log_{10} \frac{4H}{d}} \quad \text{microfarads per mile.}$$

SYSTEMS OF THREE CONDUCTORS. — Three practical examples of an electrostatically independent system consisting of three conductors only are (1) three parallel overhead wires at a distance above the earth large compared to their distances apart, (2) two wires in a lead sheath and (3) two overhead wires and the earth. In the first case any one of the three wires may be considered as the conductor of reference; in the second case it is convenient to choose the sheath of the cable as the conductor of reference, whether grounded or not, and in the third case to choose the earth as the conductor of reference. The general equations (1) and (2) are applicable to either case. Designating the reference conductor as No. 3 instead of No. 0, and the other two conductors as No. 1 and No. 2 respectively, the general equations may be written

$$\left.\begin{aligned} v_{13} &= A_{11}q_1 + A_{12}q_2, & q_1 &= B_{11}v_{13} + B_{12}v_{23}, \\ v_{23} &= A_{12}q_1 + A_{22}q_2, & q_2 &= B_{12}v_{13} + B_{22}v_{23}, \\ & & q_3 &= -(q_1 + q_2). \end{aligned}\right\} \tag{5}$$

v_{13} and v_{23} indicate the potential drop from 1 to 3 and from 2 to 3 respectively. Solving the first set of equations for q_1 and q_2 gives

$$B_{11} = \frac{A_{22}}{A_{11}A_{22} - A_{12}^2}, \quad B_{22} = \frac{A_{11}}{A_{11}A_{22} - A_{12}^2}, \quad B_{12} = \frac{-A_{12}}{A_{11}A_{22} - A_{12}^2}. \tag{5a}$$

Possible Combinations of Three Conductors which may be used as a Condenser — "Part Capacities." — The following combinations are possible:

No. 1 against† No. 2 with No. 3 insulated,
No. 2 against No. 3 with No. 1 insulated,
No. 3 against No. 1 with No. 2 insulated,
No. 1 against No. 2 and No. 3 connected together,
No. 2 against No. 3 and No. 1 connected together,
No. 3 against No. 1 and No. 2 connected together.

* When the wire is at a height large compared with the linear dimensions of its cross-section these formulas also apply approximately to wires of any shape of cross-section provided d is taken equal to the perimeter of the cross-section divided by π.

† By "against" is here meant that the source of e.m.f. is connected between the two conductors designated, e.g., in the fourth case No. 1 is charged positively say, and an equal and opposite charge divides between 2 and 3.

The capacities corresponding to these various combinations may be called "part capacities," and may be designated by subscripts thus: C_{12} = capacity of No. 1 against No. 2 with No. 3 insulated (= normal capacity between 1 and 2), $C_{1(23)}$ = capacity of No. 1 against No. 2 and No. 3 connected together (= grounded capacity of No. 1), and so on for the others. The values of these part capacities can be deduced directly from equations (5), viz.,

$$\left.\begin{aligned} C_{12} &= \frac{1}{A_{11}+A_{22}-2A_{12}}, & C_{1(23)} &= B_{11} \\ C_{23} &= \frac{1}{A_{22}}, & C_{2(31)} &= B_{22} \\ C_{31} &= \frac{1}{A_{11}}, & C_{3(12)} &= -(B_{11}+B_{22}+2B_{12}) \end{aligned}\right\} \quad (6)$$

Three Overhead Parallel Wires, Effect of Earth Neglected.—Arrangement of wires and dimensions as in Fig. 4; distance apart of wires and diameters both in the *same* unit of length, but this unit may be either centimeters or inches. From equation (20c) in the article on *Electricity and Magnetism, Principles of*, the following closely approximate values of the A's (accurate to within less than 0.1 per cent when the distance apart of the wires is greater than 10 diameters) may be deduced, taking K as unity, since the dielectric in the case under consideration is air:

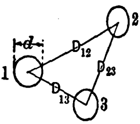

Fig. 4.

$$A_{11} = 2\log_\epsilon \frac{4D_{13}^2}{d_1 d_3}, \quad A_{22} = 2\log_\epsilon \frac{4D_{23}^2}{d_2 d_3}, \quad A_{12} = 2\log_\epsilon \frac{2D_{13}D_{23}}{d_3 D_{12}}, \quad (7)$$

all in c.g.s. electrostatic units for a length of one centimeter.*

From these relations the values of the coefficients B may be calculated for any arrangement of three parallel wires.

Equilateral Triangle Arrangement. — A common arrangement of the three wires of a three-phase transmission line is to place them so that their centers form the three vertices of an equilateral triangle. In this case $D_{12} = D_{23} = D_{13} = D$, say; and if all three wires are of the same diameter $d_1 = d_2 = d_3 = d$, say, then $A_{11} = A_{22} = 4\log_\epsilon \frac{2D}{d}$ and $A_{12} = 2\log_\epsilon \frac{2D}{d}$ in c.g.s. electrostatic units, and therefore, from equation (6) the normal capacity between any two of the wires with the third wire insulated is

$$C_{12} = \frac{1}{4\log_\epsilon \frac{2D}{d}} \quad \text{statfarads per centimeter,}$$

$$= \frac{3.677 \times 10^{-3}}{\log_{10} \frac{2D}{d}} \quad \text{microfarads per 1000 ft.,}$$

which is the same as the capacity between two parallel wires by themselves, see above.

Equilateral Triangle Arrangement with Balanced Three-phase Voltages. — For sine-wave voltages between the wires equal in effective value to V and differing in phase by 120 degrees, the above equations for the charges and

* To find the values of the B's in microfarads per 1000 feet directly from these values of the A's change 2 $\log_\epsilon$ to 136 $\log_{10}$.

charging currents give the following relations between the *effective* values of the voltages, charges and charging currents, for each of the three wires:

$$Q = C_0 V_0, \qquad I = 2\pi f C_0 V_0,$$

where

$$V_0 = \frac{V}{\sqrt{3}} = \text{voltage to neutral},$$

$$C_0 = 2\,C_{12} = \text{capacity to neutral.}$$

When the C's are in microfarads the charge Q is in microcoulombs and the charging current in micro-amperes.

The charge on any particular wire is in phase with the voltage between that wire and the neutral (*see Alternating Currents*) and the charging current for that wire is 90 degrees ahead of the voltage drop from that wire to the neutral. For the same voltage V between wires in a single-phase system as in a three-phase balanced system, the charging current per wire in the three-phase system with the equilateral triangle arrangement of wires is $\frac{2}{\sqrt{3}} = 1.155$ times the charging current per wire in the single-phase system.

For any other arrangement of wires and for an unbalanced three-phase system, the general equations (5) and the general formulas for A_{11}, A_{22} and A_{12} given above must be used.

Two-conductor Cable. — Arrangement of wires and dimensions as shown in Fig. 5. The sheath forms the conductor of reference and when designated as conductor No. 3, general equations (5), (5a) and (6) apply directly to this case also. For the symmetrical arrangement of the wires shown in the figure, $A_{11} = A_{22}$, whence, dropping the first subscript,

$$B_1 = \frac{A_1}{A_1^2 - A_2^2}, \qquad B_2 = \frac{-A_2}{A_1^2 - A_2^2}.$$

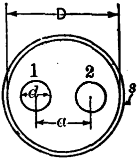

Fig. 5.

Russell (*Alternating Currents, Vol. 1*) gives the following values of A_1 and A_2, assuming a dielectric filling the space between the wires and the sheath to have the *same** specific inductive capacity throughout:

$$A_1 = \frac{2}{K}\log_e \frac{D^2 - a^2}{Dd}, \qquad A_2 = \frac{2}{K}\log_e \frac{D^2 + a^2}{2\,Da}, \tag{8}$$

both in c.g.s. electrostatic units for a length of one centimeter. To reduce to practical units for a length of 1000 ft. change $2\log_e$ to $136\log_{10}$.

Normal Capacity of a Two-conductor Cable. — Substituting Russell's values for A_1 and A_2 in equation (6) gives

$$C_{12} = \frac{K}{4\log_e\left(\frac{2a}{d}\cdot\frac{D^2 - a^2}{D^2 + a^2}\right)} \quad \text{statfarads per centimeter}$$

$$= \frac{3.677 \times 10^{-3} K}{\log_{10}\left(\frac{2a}{d}\cdot\frac{D^2 - a^2}{D^2 + a^2}\right)} \quad \text{microfarads per 1000 ft.}$$

Grounded Capacity of a Two-conductor Cable. — The capacity in this case, from equations (6), is

$$C_{1(23)} = B_{11} = \frac{A_1}{A_1^2 - A_2^2}.$$

*This is seldom realized in practice, since the dielectric is made up of insulation, fillers and braids having different specific inductive capacities; see *Wires and Cables, Insulated.*

By substituting Russell's values of the A's an approximate value for this capacity may be obtained; it will be greater than the normal capacity C_{12}.

Effect of the Earth on the Capacity of Two Overhead Wires.—As a fair approximation the earth may be considered as a conducting plane of infinite extent and the wires as parallel to this plane. Such a combination is electrostatically equivalent to two wires and their two "images" at a distance below the earth equal to the distance of the actual wires above the earth, see Fig. 6. Let q_1 and q_2 represent the charges on the actual wires and q_3 the actual charge on the earth, and V_{13} and V_{23} the potential differences between the two wires and the earth respectively (the p.d. between the two wires $v_{12} = v_{13} - v_{23}$); equations (5), (5a) and (6) then apply to this case also. The values of the A's in this case are (putting $K = 1$, since the dielectric is air)

$$A_{11} = 2 \log_\epsilon \frac{2\,D_{1a}}{d_1},\ A_{22} = 2 \log_\epsilon \frac{2\,D_{2b}}{d_2},\ A_{12} = 2 \log_\epsilon \frac{D_{1b}}{D_{12}}, \tag{9}$$

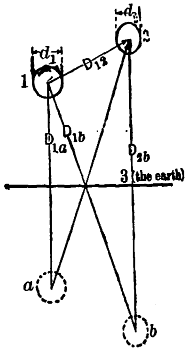

Fig. 6.

all in c.g.s. electrostatic units per centimeter length. To find the values of the B's directly in microfarads for a length of 1000 feet change 2 $\log_\epsilon$ to 136 $\log_{10}$.

Consider the special case where both wires are at the same height H, say, and both of the same diameter d; then from equation (9), putting D for the distance between their centers,

$$A_{11} = A_{22} = 2 \log_\epsilon \frac{4\,H}{d},\quad A_{12} = 2 \log_\epsilon \frac{2H}{D'}, \tag{9a}$$

where

$$D' = \frac{D}{\sqrt{1+\left(\frac{D}{2H}\right)^2}} = \text{"equivalent" distance apart.}$$

Then from equations (6)

$$C_{12} = \frac{1}{4 \log_\epsilon \frac{2\,D'}{d}} \quad \text{statfarads per centimeter.} \tag{10}$$

Comparing the formula for C_{12} with that for two wires by themselves, equation (4), it is evident that the effect of the earth in this case is to increase the capacity by an amount equal to the increase in capacity which would result from decreasing the distance between the wires from the actual distance D to the "equivalent" distance D'. For D small compared with the height H, which is usually the case, the equivalent distance D' is practically equal to D and the effect of the earth is therefore negligible.

Effect of the Earth When One Wire is Grounded.—Let No. 2 be grounded. Consider the same case as in the preceding paragraph, i.e., both wires at the same height H and of the same diameter d. From equation (5a)

$$B_{11} = B_{22} = 2C_{12}\left(\frac{A_{11}}{A_{11}+A_{12}}\right), \qquad B_{12} = -\ 2C_{12}\left(\frac{A_{12}}{A_{11}+A_{12}}\right),$$

where C_{12} has the value given by equation (10) and the A's the values given by (9a). The charge taken by conductor No. 1 is then $B_{11}v$, the charge taken

by conductor No. 2 is $B_{12}v$, and the charge taken by the earth $(B_{11} + B_{12})v$, where v is the drop of potential from No. 1 to No. 2.

Effect of the Earth When Middle or Neutral Point of the System is Grounded. — In this case $v_{23} = - v_{13}, = v_0$, where v_0 = voltage to neutral. From equation (5) it is then evident that grounding the middle point of the system has no effect upon the charging current.

SYSTEMS OF FOUR OR MORE CONDUCTORS. — The method of calculating the capacities for a three-conductor system, described in detail above, may be readily extended to a system of any number of circuits, independent or otherwise, made up of any number of conductors.

Relations Between the *A's* and *B's* for a Four-conductor System. — For a four-conductor system the relations are as follows: put

$$M = A_{11}A_{22}A_{33} + 2\,A_{12}A_{13}A_{23} - (A_{11}A_{23}^2 + A_{22}A_{13}^2 + A_{33}A_{12}^2),$$

then

$$\left.\begin{aligned} B_{11} &= \frac{A_{22}A_{33} - A_{23}^2}{M}, & B_{12} &= -\frac{A_{12}A_{33} - A_{13}A_{23}}{M}, \\ B_{22} &= \frac{A_{11}A_{33} - A_{13}^2}{M}, & B_{23} &= -\frac{A_{23}A_{11} - A_{12}A_{13}}{M}, \\ B_{33} &= \frac{A_{11}A_{22} - A_{12}^2}{M}, & B_{13} &= -\frac{A_{13}A_{22} - A_{12}A_{23}}{M}, \end{aligned}\right\} \quad (11)$$

There are 32 part capacities in the general case of a four-conductor system but in cases of symmetry they reduce to a lesser number.

Three-conductor Cable. — Arrangement and dimensions as shown in Fig. 7. The sheath forms the conductor of reference; let it be designated as conductor No. 0. From symmetry $A_{11} = A_{22} = A_{33} = A_1$, say, and $A_{12} = A_{23} = A_{13} = A_2$, say. Equations (11) then reduce to

$$B_{11} = B_{22} = B_{33} = \frac{A_1 + A_2}{(A_1 - A_2)\,(A_1 + 2\,A_2)} = B_1, \text{ say},$$

$$B_{12} = B_{23} = B_{13} = \frac{-A_2}{(A_1 - A_2)\,(A_1 + 2\,A_2)} = B_2, \text{ say},$$

and the capacity between any pair of wires is

$$C_{12} = \tfrac{1}{2}(B_1 - B_2).$$

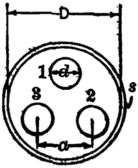

Fig. 7.

For sine-wave voltages equal in effective value and differing in phase by 120 degrees, the effective value of the charging current per wire is then, from equation (3),

$$I = 2\,\pi f\,(B_1 - B_2)\,V_0 = 2\,(2\,\pi f C_{12})\,V_0,$$

where $V_0 = \frac{V}{\sqrt{3}}$, the voltage V being the p.d. between wires. This current leads the voltage drop to neutral, V_0, by 90 degrees.

Calculated Value C_{12} for a Three-conductor Cable. — Russel (*Alternating Currents, Vol. 1*) gives the following approximate values for A_1 and A_2, assuming the insulation fillers and braids to have the same specific inductive capacity (which is not usually the case),

$$A_1 = \frac{0.1360 \times 10^9}{K} \log_{10}\left(\frac{D^2 - 1.33\,a^2}{Dd}\right) \text{ and } A_2 = \frac{0.0680 \times 10^9}{K} \log_{10}\left(\frac{0.75\,D^6 - 1.78\,a^6}{a^2D^2\,(3\,D^2 - 4\,a^2)}\right)$$

in practical units for a length of 1000 feet. Using these values the normal capacity between wires is

$$C_{12} = \frac{3.677 \times 10^{-3} K}{\log_{10} \frac{2\,a\rho}{d}} \quad \text{microfarads per 1000 feet,}$$

where

$$\rho = \sqrt{\frac{(3\,D^2 - 4\,a^2)^3}{(3\,D^2)^3 - (4\,a^2)^3}}.$$

That is, the capacity is the same as that of two parallel wires by themselves but at a distance ρa between centers instead of the actual distance a.

Effect of the Earth on the Capacity of Three Overhead Wires. — For any kind of arrangement, as shown in Fig. 8 (the dotted circles are the "images" of the actual wires), the general expressions for the A's in c.g.s. electrostatic units * for a length of one centimeter are as follows:

$$A_{11} = 2 \log_\epsilon \frac{2\,D_{1a}}{d_1}, \quad A_{22} = 2 \log_\epsilon \frac{2\,D_{2b}}{d_2}, \quad A_{33} = 2 \log_\epsilon \frac{2\,D_{3c}}{d_3},$$

$$A_{12} = 2 \log_\epsilon \frac{D_{1b}}{D_{12}}, \quad A_{13} = 2 \log_\epsilon \frac{D_{1c}}{D_{13}}, \quad A_{23} = 2 \log_\epsilon \frac{D_{2c}}{D_{23}}.$$

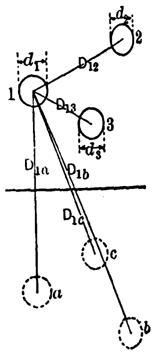

Fig. 8.

The values of the B's may then be calculated from equation (11) and the charging currents from equation (3). For any numerical case the calculations are tedious, but not difficult. Ordinarily the formulas given above neglecting the effect of the earth are sufficiently accurate for all practical purposes; compare with the effect of the earth on a two-wire line.

Electrostatic Induction From One Circuit to Another. — The general equations (1), (2) and (3) together with the method of calculation of the A's given in the last paragraph make it possible to calculate the induced voltages from one line to another, e.g., the voltages induced from a high-tension line to a telephone line. The method is straightforward, but tedious. The discussion given above indicates how such a problem may be attacked; space is not available for a detailed discussion here.

BIBLIOGRAPHY. — Russell, Alex., *Alternating Currents*, London, 1906; Ferguson, *Elements of Electrical Transmission*, N. Y., 1911; Perrine, *Conductors for Electric Distribution*, N. Y., 1907.

* To find from these A's the values of the B's in microfarads per 1000 feet change $2 \log_\epsilon$ to $136 \log_{10}$.

[H. PENDER.]

CAR BARNS AND INSPECTION SHEDS. — (*See also Cars, Electric; Locomotives, Electric; Railways.*) In every electric railway system it is necessary to provide car barns and inspection sheds where the cars may be taken regularly for a systematic inspection. In some cases these barns are used for the storage of cars and in special cases are equipped as regular repair shops. Provision for inspection is necessary, provision for storage is optional, although it is customary to provide storage at least for those cars which are idle during the daytime. The expense of providing for the storage under cover of all the cars that are idle between midnight and 6 a.m. is of doubtful value, for the deterioration of the cars left in the open is likely to be less than the fixed charges on the increased capacity of the sheds. The extent to which repairs are made by the railway company differs according to the policy and size of the road, and thus the size of the repair shop varies considerably.

Location. — The location of the car barn may be determined by several considerations. It may be located in the city on account of the convenience of the employees, the possibility of placing the general offices in the same building, and on account of the fact that the city service is an important part of the whole system. It may be located in the suburbs where real estate is cheap and ample space available. It may be located at a convenient point such as the center of gravity of the system, so that the dead mileage of the cars will be a minimum. Finally, it may be located adjacent to the power station, so that the repair shops of the two departments may be combined and thus become more efficient.

Danger of Fire. — Wherever the car barn is located considerable attention should be given to the possibility of fire and it should be detached from all neighboring buildings, particularly those of a hazardous character, as the danger from fire in a car barn is very great. There should be available a sufficient supply of water for fire protection and the building should be equipped with automatic fire sprinklers.

Lay-out Tracks, Inspection Pits, etc. — In arranging the scheme of tracks consideration is given to the convenience of getting cars in and out past cars undergoing repairs, and without interfering with the main-line traffic. It is also well to make provisions for getting all the cars out of the barn quickly in case of fire, and for this purpose the tracks are sometimes inclined towards the exits so that the cars will run out by gravity when the brakes are released. A transfer table on which a car may be run and transferred laterally to any track in the barn is sometimes provided, and to avoid wasting the space that the pit for such a table would occupy, the table is frequently operated on tracks at the same level as that of the main tracks. In this case the cars must mount a slight incline to get upon the table. A great many motors, particularly those used on city cars and single-truck cars, are of the split-frame type, which are inspected by swinging the lower half of the frame downward. To inspect these motors a pit is required of sufficient depth for a man to work comfortably underneath the cars, and with provision for illumination both general and by drop light. The illumination of a car barn should be both general and local. The general illumination should consist of incandescent lights suspended from overhead between the tracks and spaced about a car length apart. These may be run five in series on the trolley circuit, although an ungrounded system is better. The intensity of illumination on the floor should be from 1 to 1.5 foot-candles or lumens per square foot. Frequent sockets for drop lights must also be provided for many portions of the car equipment are in dark corners.

Repair Shops. — While some roads only make very minor repairs to their cars others maintain very complete repair shops so that general recommendations are difficult to make. Harding, in *Electrical Railway Engineering*, gives the following list of tools as desirable, named in order of importance:

1 screw-cutting lath, 14-inch swing.
1 vertical drill press, 24 inches.
1 tool-grinding wheel.
1 armature stand for rewinding armatures.
2 forges.
1 automatic-power hack saw.
1 oven for baking insulation.
1 commutator slotting machine.
1 wheel-turning lath.
1 hydraulic-wheel press.

[W. I. SLICHTER.]

CARS, ELECTRIC. — (*See also Control Systems for Railway Motors; Collectors, Current; Locomotives, Electric.*) The cars used on electric railways have developed rapidly but gradually from the small two-axle car with one motor on the platform geared to the axle by a chain, to the large steel double-truck car now used in high-speed interurban service. Cars may be divided into two classes, viz., single-truck and double-truck. Each of these classes may be subdivided into types according as the cars are open or closed.

SINGLE-TRUCK CARS have a seating capacity as high as 32 passengers. Their characteristics are given in the accompanying table.

Item	Dimension
Over-all length	28 to 31 ft.
Rigid wheel base	5 to 7 ft.
Weight loaded and equipped	12 to 20 tons
Maximum speed	25 m.p.h
Maximum motor capacity, total	80 h.p.
Number of motors	2

They are only used in city service with frequent stops and usually have a cylinder-type controller at each end with hand brakes, although there are cases where these cars have been fitted with remote control and air brakes.

Considerable attention is being given at present to the subject of equipping these cars so that during the hours of heavy traffic they may be run in trains of two, controlled by one motorman. This causes less congestion in the streets for a given service and obviates the waste of operating throughout the day cars of large capacity designed to meet rush-hour conditions.

DOUBLE-TRUCK CARS.— The double-truck type of car has an over-all length of from 30 to 70 feet, a seating capacity of from 32 to 70 passengers and a maximum speed of from 40 to 70 m.p.h. One of these cars consists of a body mounted on two, four-wheel trucks. The car body under-frame is supported on a cross piece in the truck known as the bolster and is kept in position by a king-pin fitted into a king-pin center plate on the car body. The truck may swivel around this king-pin through quite an angle, guided by curved plates on each member.

Construction of Trucks. — The truck consists of axles, carried in journal boxes in side frames, transoms which connect the side frames, and the bolster which is carried by the transoms by means of springs (either spiral or elliptical) and a spring plate swung from the transoms. Coil springs are inserted between the journals and the side frames. The bolster may be of the "rigid," "floating" or "swinging" type depending upon the amount of play in the bolster. The rigid bolster is employed in locomotives only. The swinging bolster is most generally used for passenger cars, particularly in high-speed service, as it makes a much more easy riding construction. The three-axle truck is common in high-speed steam railroad practice, but the two-axle truck is generally used in electric railway practice as it allows more room for the motors. Four-wheel trucks are sometimes called "bogie" trucks or "swiveling" trucks to distinguish them from the "pony" or "radial" trucks having two wheels, which are used on steam locomotives.

Motor-car trucks have wheels of from 33 to 36 inches in diameter, and usually weigh from 10,000 to 15,000 pounds depending upon the size of the motors and body they are intended to carry. The rigid wheel base is from 6 to 8 feet.

The problem of making a motor-driven truck guide properly is considerably more difficult than guiding the trucks of a car that is hauled, as there is a tendency for the motor-driven truck to get out of line and become cramped between the rails. On this account and on account of the weight of the motors, trucks for a motor car must be stronger and heavier than for a trailer car.

Suspension of Motors. — The motors are usually hung between the axles on a single-truck car and between each axle and the transom on a double-truck car. In the "nose" suspension a lug is cast on the side of the motor frame away from the axle and this is attached to the transom with or without springs. The other side of the motor is carried by arms containing bearings which encircle the car axles. Thus about one-half of the weight of the motor is carried as a dead weight on the car axle, and the rest by the truck framing. In the "cradle" suspension both motors of a truck are carried by a cradle which is suspended from the car axles by springs. By this arrangement the entire weight of the motors is spring supported and carried by the axles, thus relieving the transom and side frames of the weight of the motors.

Maximum Traction Truck. — This is a special form of bogie truck with two axles having wheels of different diameters. The equalizing arrangements in this truck are such that about three-quarters of the total weight comes on the main axle which has the larger wheels and carries the motor, and the balance comes on the other axle which has small wheels. This arrangement gives a double-truck car with only two motors and yet provides that about three-quarters of the total weight shall be on driving axles, thus yielding "maximum traction." This type of truck is used on cars which are too long and heavy to use the two-axle rigid truck but which have such slow speed that only two motors are required. It is not adapted to high-speed work.

CAR BODIES may be classified as closed, convertible, semi-convertible and open.

Closed Cars.— The small closed type for city service is always of wood and has longitudinal seats. The general dimensions are given in the table below. Large closed cars with double trucks for interurban or rapid-transit service have both transverse and longitudinal seats, the proportion depending upon the proportion of long-haul traffic. The longitudinal seats give an arrangement permitting convenience of movement into and out of the car and allow more room for standing, but are not comfortable for long trips. Transverse seats are more comfortable for a long trip and for a service employing a high rate of acceleration.

Convertible Cars are constructed so that all the side panels of the body may be folded either up into the roof, or down to the floor leaving only the upright posts carrying the weight of the roof, thus converting a closed car into an open car at will.

Semi-convertible Cars. — A semi-convertible car, as its name implies, is arranged so that it may be partly opened in the summer time. It makes a very good car for high-speed interurban service because it is not advisable to operate open cars in high-speed service.

Open Cars usually have the transverse seats extending clear across the car. Access is obtained by steps running the length of the car on each side. They may be of the single- or double-truck type. They provide the maximum seating capacity for a given weight.

Cars for Rapid Handling of Traffic. — In large cities where the service is congested special means must be provided to aid and direct the rapid loading and unloading of cars. In a rapid transit service having stations this is accomplished by placing doors in the sides of the cars at the center and at or near the ends, and requiring all passengers to enter by the end doors and leave by the

center doors. Both center and end doors are operated by compressed air and controlled by a guard at one end of the car. For street service the pre-payment or "pay as you enter" car is employed. This is built with extra long platforms at each end. The passengers are required to deposit their fare in a box as they enter the car from the rear platform, where the conductor stands, and to leave by the front door and platform. The rear platform is made roomy to take care of congestion while the conductor is making change. Cars of this type recently installed in Chicago and Philadelphia are arranged for both entrance and exit of passengers at the front end, the conductor's station also being at this end.

Construction of Car Bodies. — Most of the car bodies used on electric railways are constructed of wood, but for underground roads or for roads operating a high-class suburban service of multiple-unit trains the cars are preferably constructed of steel to reduce the dangers from collision and fire. This construction is demanded by consideration of safety but it is directly contrary to the general tendency of the present day to reduce the weight of cars as much as possible. The proportion of weight of car to weight of load is very high and it entails a considerable waste of energy to propel this dead weight. The weight of car per passenger or seat capacity is a figure that should receive careful consideration and it should be kept at the minimum value compatible with strength and safety.

DIMENSIONS AND WEIGHTS OF TYPICAL EQUIPMENTS. — There are indicated in the following table the principle data for electric cars which are being operated in various typical services.

Service	City	City	City	City P. A. Y. E.	Suburban	Interurban	Subway	N. Y. C. R.R.	W. S. R.R.
Seating capacity	14	24	32	32	38	40	52	64	52
Number of trucks	1	1	1	2	2	2	2	2	2
Length over-all, ft.	22	30	32	41	38	40	50	60	49
Length of body, ft.	16	20	21	28	28	29	41	50	38
Number of motors	2	2	2	2	2	4	2	2	4
H.p. of each motor	40	40	40	70	70	50	200	200	75
Weight of body, lb.	6,000	9,530	7,500	15,800	15,670	19,200	34,300	55,000	35,110

[W. I. SLICHTER.]

CASTINGS, IRON AND STEEL. — These are made by pouring the molten material into sand or iron molds of the desired shape and allowing it to cool. Sand molds are generally used, and are made by packing molding sand about a wooden pattern having the shape of the desired casting and somewhat larger dimensions to allow for the contraction of the metal in cooling. The removal of the pattern leaves a hollow in the sand of the shape of the object to be cast. In order to have sufficient consistency the sand should either contain some clay and be somewhat moist, giving a "green sand" mold, or it should be mixed with a binding material giving a "dry sand mold."

Simple patterns may be made in one piece, but if the pattern be at all complicated it must be made in two or more pieces to permit withdrawal from the sand without disturbing the latter.

Steel castings are more difficult to make than iron castings, as they are more porous; thin steel sections should be avoided for such castings, as the steel cools too rapidly when thin.

In all castings sudden changes in the thickness of the metal should be avoided, as the unequal cooling of sections of different thicknesses causes temperature stresses and may crack the metal. This is particularly true in steel castings.

Care should be exercised in designing castings to make them such that the patterns can be readily removed from the sand molds.

Process of Making a Mold. — A wooden or iron box called a flask, consisting of sides only, is used in making the molds. This is divided into a bottom portion called the drag, and an upper portion called the cope; see Fig. 1. Intermediate portions, called checks, are used for complicated patterns.

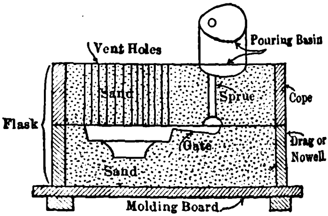

Fig. 1.

A hole is made through the cope to convey the metal to the mold. Molds made of "dry sand" should be baked in an oven before pouring. The surface of the mold is frequently coated with "blacking."

If holes are to be made in the casting they are formed by cores of hard-baked sand inserted after the pattern is removed and are held in place by studs of metal, called "chaplets," and by impressions in the mold made by projections on the pattern called "prints."

Cost of Iron and Steel Castings. — The cost of an iron casting, exclusive of the pattern, depends somewhat upon the intricacy of the pattern; representative costs in 1914 were for simple patterns of moderate size, 3 to 5 cents per pound; for large engine and dynamo castings 3 to 4.25 cents per pound; for small intricate castings 6 to 10 cents per pound. Malleable iron castings cost about 10 to 25 per cent more, and steel castings about 50 to 100 per cent more.

BIBLIOGRAPHY. — See bibliographies in the articles on *Iron, Pig and Cast; Steel.*

[C. M. SPOFFORD.]

CELLS, STANDARD. — (*See also Batteries, Primary; Electrochemistry, Principles of; Potentiometers.*) The need of a standard of electromotive force was recognized in the early days of the electrical industry, and the Daniell cell (*see Batteries, Primary*) was largely used for this purpose. This cell is readily prepared from ordinary chemicals, and is still used to some extent as a rough and ready standard. Such a cell, however, deteriorates quite rapidly, and has therefore been supplanted, for all accurate measurements, by other cells which possess to a greater degree the necessary characteristics of permanence and reproducibility. There are at present two types of standard cells in general use, the Clark and the Weston cells. The latter is the more generally used at the present time.

Pure Chemicals Required. — In order that the e.m.f. of any form of primary standard cell may accord with the stated value, great care must be exercised in the preparation of the materials, the processes for which have been carefully worked out by Kahle and later by Wolff and Waters (*Bull. Bureau of Standards, 1907, Vol. 4, p. 1*).

CLARK CELL. — In Fig. 1 is shown the Kahle's H-form of the Clark cell, which is one of the most satisfactory of the several forms in which the Clark cell is made. The container is of glass, which is mounted in a metal case with insulated binding posts connected to the two platinum terminals. The saturated solution of zinc sulphate forms the electrolyte, the paste of mercurous sulphate and zinc sulphate acts as a depolarizer, the mercury forms the positive pole and the zinc the negative pole. Detail directions for the preparation of the cell are given in the Bulletin of the Bureau of Standards, 1907, Vol. 4, p. 1.

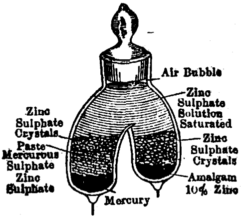

Fig. 1. Kahle's H-form of Clark Cell

Electromotive Force of Clark Cell. — The e.m.f. of the Clark cell, as determined at the time of the adoption of the international units (*see Units, Practical Electrical*), was given as 1.434 volts at 15° C. Subsequent investigations have shown that its true value is 1.4328 international volts at 15° C. At any other temperature $t°$ C. its e.m.f. is

$$E_t = 1.4328\,[1 - 0.00077\,(t - 15)].$$

The chief objections to the Clark cell are its relatively high temperature coefficient and the length of time required for the e.m.f. to attain a constant value after a change in the temperature of the cell.

Carhart-Clark Cell. — To reduce the temperature coefficient and time lag of the saturated or "normal" Clark cell, Carhart devised a form of Clark cell in which the zinc sulphate solution was just saturated at 0° C. with no excess of crystals. The e.m.f. of this type of cell is approximately

$$E = 1.440\,[1 - 0.00039\,(t - 15)].$$

For accurate work, however, such cells must be calibrated, as the e.m.f. of individual cells may differ appreciably.

WESTON OR CADMIUM CELL. — In Fig. 2 is shown the construction of the "normal" Weston or cadmium cell. The container is of glass suitably mounted in a case provided with binding posts to which the platinum wires are attached. This cell differs from the Clark cell chiefly in the use of cadmium amalgam and cadmium sulphate in place of the zinc amalgam and zinc sulphate

for the negative pole and electrolyte respectively. The particular advantage in the use of cadmium instead of zinc arises from the low temperature coefficient and small temperature lag thus obtainable. It also has a longer life and polarizes less rapidly than the Clark cell.

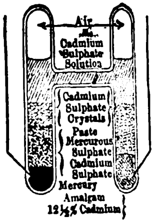

Fig. 2. Weston Cell

Electromotive Force of Weston Normal Cell. — The e.m.f. at 20° C. of the Weston normal cell (the word normal designating that the cadmium sulphate solution is saturated) is 1.0830 international volts. At any other temperature t° C. its e.m.f. is

$$E_t = 1.01830 - 10^{-6}[40.6\,(t-20) + 0.95\,(t-20)^2 + 0.001\,(t-20)^3].$$

(*See Bulletin Bureau of Standards, 1909, Vol. 5, p. 309.*) The e.m.f.'s of normal cadmium cells as set up by various observers following the same specifications differ among each other by less than 1 part in 10,000.

Weston Secondary Standard Cell. — The Weston Instrument Co. make a portable form of cadmium cell, which differs from the normal cadmium cell chiefly in that the cadmium sulphate solution is just saturated at 4° C., and therefore does not contain an excess of cadmium sulphate crystals at ordinary temperatures. This type of cell is to be used between the temperatures of 4° and 40° C. The temperature coefficient is much smaller than that of the normal cell and is negligible for any ordinary measurements; each cell is accompanied by a certificate stating its e.m.f. The extreme variation among 145 cells of this type was found to be 0.0009 volt. This is at present the best form of secondary standard cell, being remarkably permanent. The e.m.f. is approximately 1.0186 international volts; the resistance, roughly, 200 ohms.

PRECAUTION IN USING STANDARD CELLS. — No appreciable current can be taken from a standard cell without alteration of its e.m.f., due to polarization. It is found that the change is not permanent, for the cell gradually recovers its original e.m.f.; of course the cell is unreliable until the recovery is complete. Consequently standard cells should be used only where their e.m.f. is opposed to an equal p.d., as in connection with potentiometers. They should always be protected by a key, which is closed only momentarily, and for preliminary adjustments a high resistance, several thousand ohms at least, should be in series with the cell. When an approximate balance has been obtained this resistance should be cut out and the final balance then made.

COSTS. — A normal Clark cell costs about $12, a normal cadmium cell $15, a portable Weston cell $15.

[H. Pender and H. R. Ranken.]

CEMENT. — (*See also Concrete.*) The cements used in engineering construction are Portland, natural and Puzzolan (or slag) cements. Of these Portland cement is the most reliable and should always be used in reinforced concrete construction. The processes of manufacture and general characteristics of these cements are given in the following paragraphs, the descriptions being copied from the report of the Joint Committee as published in *Proc. Am. Soc. C. E.*, Feb., 1913.

PORTLAND CEMENT. — This is the finely pulverized product resulting from the calcination to incipient fusion of an intimate mixture of properly proportioned argillaceous and calcareous materials. Portland cement should be used in reinforced concrete construction and in any other construction that will be subject to shocks or vibrations or stresses other than direct compression.

Specifications. — The following specifications are taken by permission from the 1912 *Year Book of the Am. Soc. Test. Mat.*

Specific Gravity. — The specific gravity of cement shall be not less than 3.10. Should the test of cement as received fall below this requirement, a second test may be made on a sample ignited at a low red heat. The loss in weight of the ignited cement shall not exceed 4 per cent.

Fineness. — Portland cement shall leave by weight a residue of not more than 8 per cent on the No. 100, and not more than 25 per cent on the No. 200 sieve.

Time of Setting. — It shall not develop initial set in less than 30 minutes; and must develop hard set in not less than one (1) hour, nor more than ten (10) hours.

Tensile Strength. — The minimum requirements for tensile strength in pounds for briquettes 1 sq. in. in cross-section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Age	Neat cement	One part cement, three parts standard Ottawa sand
24 hours in moist air	175	....
7 days (1 day in moist air, 6 days in water)	500	200
28 days (1 day in moist air, 27 days in water)	600	275

Constancy of Volume. — Pats of neat cement about 3 in. in diameter, ½ in. thick at the center, and tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(*a*) A pat is then kept in air at normal temperature and observed at intervals for at least 28 days.

(*b*) Another pat is kept in water maintained as near 70° Fahr. as practicable, and observed at intervals for at least 28 days.

(*c*) A third pat is exposed in any convenient way in an atmosphere of steam, above boiling water, in a loosely closed vessel for 5 hours.

These pats, to pass the requirements satisfactorily, shall remain firm and hard, and show no signs of distortion, checking, cracking or disintegrating.

Sulphuric Acid and Magnesia. — The cement shall not contain more than 1.75 per cent of anhydrous sulphuric acid (SO_3) nor more than 4 per cent of magnesia (MgO).

NATURAL CEMENT. — This is the finely pulverized product resulting from the calcination of an argillaceous limestone at a temperature only sufficient to drive off the carbonic acid gas. Natural cement does not develop its strength as quickly, nor is it as uniform in composition, as Portland cement. Natural cement may be used in massive masonry where weight rather than strength is the essential feature. Where economy is the governing factor, a comparison may be made between the use of natural cement and a leaner mixture of Portland cement that will develop the same strength.

Specifications. — The following specifications are taken from the 1912 *Year Book of the Am. Soc. Test. Mat.* by permission.

Fineness. — Natural cement shall leave by weight a residue of not more than 10 per cent on the No. 100, and 30 per cent on the No. 200 sieve.

Time of Setting. — It shall not develop initial set in less than 10 min., and shall not develop hard set in less than 30 min., or in more than 3 hours.

Tensile Strength. — The minimum requirements for tensile strength in pounds for briquettes 1 sq. in. in cross section shall be as follows, and the cement shall show no retrogression in strength within the periods specified:

Age	Neat cement	One part cement, three parts standard Ottawa sand
24 hours in moist air	75	....
7 days (1 day in moist air, 6 days in water)	150	50
28 days (1 day in moist air, 27 days in water)	250	125

Constancy of Volume. — Pats of neat cement about 3 in. in diameter, ½ in. thick at the center, tapering to a thin edge, shall be kept in moist air for a period of 24 hours.

(*a*) A pat is then kept in air at normal temperature.
(*b*) Another is kept in water maintained as near 70° Fahr. as practicable.

These pats are observed at intervals for at least 28 days, and, to pass the tests satisfactorily, should remain firm and hard and show no signs of distortion checking, cracking or disintegrating.

PUZZOLAN OR SLAG CEMENT. — This is the finely pulverized product resulting from grinding a mechanical mixture of granulated basic blast-furnace slag and hydrated lime. Puzzolan cement is not nearly as strong, uniform nor reliable as Portland or natural cement, is not used extensively, and never in important work; it should be used only for foundation work underground where it is not exposed to air or running water.

COST OF CEMENT. — As the cost of transportation is an important item in the cost of cement, the market price depends largely upon the place of sale. Quotations are given in the first number each month of *Engineering News*. The following prices are from the issue of this paper for June 5, 1913.

Portland cement at New York,	$1.58 per bbl. in wood with 40 cents rebate on return of barrel.
Portland cement at Los Angeles,	$1.25 per bbl. in bulk at mill.
Portland cement at Chicago,	$1.05 per bbl. in bulk at mill.
Portland cement at Boston,	$1.72 per bbl. in wood with 40 cents rebate on return of barrel.
Portland cement at Boston,	$1.42 per bbl. in paper (4 bags = 1 bbl.).
Portland cement at Pittsburg,	$1.58 per bbl. in bags, with 10 cents per bag rebate on return.
Natural cement at New York,	$0.95 per bbl.
Natural cement at Boston,	$1.15 per bbl.

BIBLIOGRAPHY. — See *Bibliography* in article on *Concrete*.

[C. M. SPOFFORD.]

CHAINS AND CHAIN DRIVE. — Chains for hoisting and similar purposes may be made with straight open links, twisted links or with links with transverse studs to prevent the links from collapsing under heavy loads. These types of chains are known as straight-link chains, twisted chains and stud chains, respectively. The twisted chain is usually employed when the chain has to be wrapped around a smooth drum. Crane chains are straight-link chains carefully made to fit the corrugations of the winding drum.

Chains for transmitting power are of various forms. The more common types are block chains, roller chains and various makes of "silent" chains. In all these chains the links are made of several pieces of metal, the longitudinal pieces being riveted, bolted or screwed to the end pieces or studs. In the block chain, an example of which is the ordinary bicycle chain, the end pieces are solid blocks of metal; in the roller chain the end pieces form studs which carry small rollers. With block or roller chains the power is transmitted from or to the sprocket directly by the studs or rollers, whereas in the various types of "silent" chains, e.g., the Morse and Renold chains, the longitudinal pieces of the links are provided with lugs or fingers which mesh with the teeth of the sprocket wheel and thus pull it around.

Link belts are essentially power transmitting chains made by mounting a number of single chains side by side, so that they all move as a unit. Link belts are used both for power transmission and for belt conveyors.

DATA ON ORDINARY CHAINS (*Penn. R.R. Specifications, 1903*)

Nominal diameter of wire, inches	Description	Maximum length of 100 links, inches	Weight per foot, lb.	Proof test, lb.	Breaking weight, lb.
5/32	Twisted	103 1/8	0.20	....	....
3/16	Twisted	96 1/4	0.35	....	....
3/16	Perfection twisted	151 1/4	0.27	....	....
1/4	Straight-link	102	0.70	1,600	3,200
5/16	Straight-link	114 3/4	1.10	2,500	5,000
3/8	Straight-link	114 3/4	1.60	3,600	7,200
3/8	Crane chain	113 5/8	1.60	4,140	8,280
7/16	Straight-link	127 1/2	2.07	4,900	9,800
7/16	Crane	126 1/4	2.07	5,635	11,270
1/2	Straight-link	153	2.50	6,400	12,800
1/2	Crane	151 1/2	2.60	7,360	14,720
5/8	Straight-link	178 1/2	4.08	10,000	20,000
5/8	Crane	176 3/4	4.18	11,500	23,000
3/4	Straight-link	204	5.65	14,400	28,800
3/4	Crane	202	5.75	16,560	33,120
7/8	Crane	252 1/2	7.70	22,540	45,080
1	Crane	277 3/4	9.80	29,440	58,880

1 1/8	Crane	303	12.65	38,260	76,520
1 1/4	Crane	353 1/2	15.50	46,000	92,000
1 1/2	Crane	416 5/8	22.50	66,240	132,480
1 3/4	Crane	479 3/4	30.00	90,160	180,320
2	Crane	555 1/2	39.00	117,760	235,520

SIZE, PITCH, STRENGTH AND WEIGHT OF CHAINS. — The size of an ordinary chain in which the links are made of wire or rods is specified by the diameter of the wire or rod. The pitch of a chain is the distance between the centers of successive links, usually expressed in inches. The proof test of a chain is the specified load it must carry without deformation, and is usually taken as one-half the breaking load. The ordinary safe load is usually taken as about two-thirds of the proof test, or one-third the breaking load.

The safe working load is dependent on the amount of rivet-bearing surface, speed, size of sprockets, etc., and ranges from 1/5 to 1/40 of the tensile strength.

STRENGTH OF ROLLER AND BLOCK "DIAMOND" CHAINS

Pitch, inches	Tensile strength, pounds	
	Roller	Block
1/2	1,200	....
5/8	1,200	....
3/4	4,000	....
1	6,000	1200–2500
1 1/4	9,000	....
1 1/2	12,000	5000
1 3/4	19,000	....
2	25,000	....

CHAIN DRIVE. — The advantages of chain drive are positive speed ratio, capability of transmitting large amounts of power at low speeds, not seriously affected by moisture, oil or grease, no stretch, and for short transmissions greater efficiency than leather, rubber or fiber belting. Roller chains should not as a rule be run at speeds of over 1000 feet per minute, and block chains not over 700 feet per minute.

Wherever possible, the distance between centers of shafts should permit of adjustment in order to regulate the sag of the chain. A chain should be adjusted, in proportion to its length, to show slack when running, care being taken to have it neither too tight nor too loose, as either condition is destructive.

The principal cause of trouble within the chain itself is elongation. It is the result of stretch of material or natural wear. Sudden jars or jolts beyond the limit of elasticity of the material will quickly render the chain useless. If for any reason a link elongates unduly it should be replaced at once, as one elongated link will eventually ruin the entire chain.

To minimize wear, chains should be kept well greased and protected from mud and grit, cleaned often, and when replaced put back so that they run in the same direction and same side up. A new chain should never be applied to a much-worn sprocket.

Sprockets. — Properly proportioned and machined sprockets are essential to successful chain gearing. For block chain these are obtained as follows:

Sprockets should be gauged to discover thick teeth and inaccurate diameters. A poor chain may operate on a good sprocket, but a bad sprocket will ruin a good chain. Sprockets of 12 to 60 teeth give best results. Fewer may be used, but cause undue elongation in the chain, wear the sprockets and consume too much power. Eight-tooth sprockets ruin almost every roller chain applied to them, and ten and eleven teeth are fitted only for medium and slow speeds with other conditions unusually favorable.

[WM. KENT.]

CHIMNEYS. — (*See also Draft, Mechanical.*) A chimney serves as a means for establishing a sufficient draft through a furnace to produce the combustion of the fuel. The amount of air *required* per hour depends upon the quantity of fuel burned per hour and the quality of fuel. The amount actually used depends also on the manner of firing, or the judgment and skill of the fireman. The *force required* to produce this draft in turn depends upon the quality of the fuel, the method of firing, the thickness of the fuel bed, the design of the furnace, the length and cross section of the gas passages, the height and cross section of the chimney, the location of the chimney with respect to neighboring buildings and hills, and the direction and velocity of the wind which may be blowing. The *force available* for producing the draft depends upon the height and cross section of the chimney and the difference in temperature of the hot gases in the chimney and the cold air outside. On account of the number of these variables and their great range of variation from time to time, it is practically impossible to deduce a rational formula for the size of the chimney required for the combustion of fuel at a given rate. The following approximate method for determining the height and cross section of a chimney, however, has been found satisfactory in practice. The formula connecting the height, cross section and rate of fuel consumption is an empirical one, deduced by the author from numerous actual cases, and first published in 1884. It has been extensively employed with satisfactory results by numerous engineers since that time.

INTENSITY OF DRAFT AND HEIGHT. — The difference in weight between the hot gases inside the chimney and the weight of an equal column of the external air is the cause of the draft produced by the chimney. The pressure due to this difference is called the "intensity" of the draft and is usually measured in inches of water column required to balance it. The measurement is made by a draft gauge, usually a U-tube partly filled with water, one leg connected by a pipe to the interior of the flue between the boiler and chimney and the other open to the external air. For finer and more accurate readings some form of multiplying gauge is used.

Let t_1 be the average temperature of the chimney gases, t_2 the temperature of the external air, both in degrees Fahrenheit, and let H be the height of the chimney in feet. Then the total intensity of draft produced by the chimney, expressed in inches of water column for normal atmospheric pressure, is

$$F = H\left(\frac{7.64}{460 + t_2} - \frac{8.00}{460 + t_1}\right).$$

For an atmospheric pressure of P inches of mercury, multiply the left-hand side by $\frac{P}{30}$.

The intensity of the draft and consequently the velocity and the volume of the hot gases will of course be greater the greater the temperature of the hot gases, but as the temperature increases the volume of a given weight increases, that is, their density decreases. When the temperature of the gases exceeds a certain value the increase in the velocity due to a further increase of temperature will be more than offset by the decrease in density. According to Rankine the temperature corresponding to the maximum value of the product of volume and density, that is the maximum weight of gases discharged, is, under ordinary conditions, 600° F., when the external temperature is 60°. Hence the total intensity of draft F_0 corresponding to maximum weight of discharged gases may be found approximately by substituting 600 in the above formula for t_1, and 60 for t_2. The formula then reduces to $F_0 = 0.007\ H$.

The actual intensity of the draft is usually less than that calculated from the

temperature taken at the bottom of the chimney, on account of the cooling of the gases as they ascend in the chimney and other causes. Taking the reduction at 20 per cent the formula expressing the relation of intensity of draft to height of chimney becomes $F_n = 0.0057\, H$ on the assumption of a temperature of 600° at the bottom of the chimney.

MINIMUM HEIGHT. — Hence when the intensity of the draft necessary to produce the necessary current of air through the breeching, boiler and furnace is known, the minimum height of chimney which will produce this draft is

$$H = 175\, F_n \text{ feet,}$$

where F_n is the net intensity of draft in inches of water required.

The net intensity of draft required depends upon the resistance of the gas passages between the ash pit and base of stack. Gebhardt gives the following approximate rules, which, however, should be used only as a very rough guide, since the loss of draft in the various parts of the gas passages depends upon the size and shape of these passages, the velocity of the gases, etc.

Loss of draft in breeching: 0.1 inch of water column per 100 feet of flue.

Loss of draft in breeching: 0.05 inch for each right angle bend.

Loss of draft in boiler: 0.2 to 0.4 inch, depending upon type of boiler.

Loss of draft in furnace: depends upon the kind of coal, the kind of grate, the caking, the clinker, the thickness of the bed of coal and the area of the grate. The loss of draft is greatest with small anthracite coal (No. 3 Buckwheat) and least for high-grade bituminous coal. The following table, from curves published by the Stirling Co., gives roughly the loss of draft in the furnace which may be expected under average conditions.

APPROXIMATE LOSS OF DRAFT BETWEEN ASH PIT AND FURNACE, INCHES OF WATER

Lb. of coal per sq. ft. grate surface per hour	10	15	20	25	30	40	50
No. 3 buckwheat	0.4	0.8	1.3	....	....	....	....
No. 1 buckwheat	0.2	0.4	0.7	1.0	....	....	....
Pea coal	0.15	0.3	0.5	0.7	0.9	....	....
Semi-bituminous (run of mine)	0.1	0.15	0.2	0.3	0.4	0.6	1.0
Bituminous (slack)	0.07	0.1	0.15	0.2	0.3	0.4	0.6
Bituminous (run of mine)	0.05	0.08	0.10	0.15	0.2	0.3	0.4

Example: Find the minimum height of chimney for a boiler burning 30 pounds of bituminous run-of-mine per hour per square foot of grate surface, the flue being 100 feet long with two right angle bends

$$F_n = 0.1 + 2 \times 0.05 + 0.4 + 0.2 = 0.8,$$

assuming a loss of 0.4 inch in the boiler

$$H = 170 \times 0.8 = 136 \text{ feet.}$$

In any particular case the loss of draft in the various parts of the gas passages may differ considerably from the figures given above, and consequently the height of chimney calculated on the above assumptions should be looked upon

merely as a rough approximation. The final design of the chimney should be left to an engineer of experience in this kind of work.

According to C. L. Hubbard (*Am. Elec., Mar., 1904*), the following heights have been found to give good results in plants of moderate size (500 horse-power or less), with sufficient draft to force the boilers 20 to 30 per cent above their rating:

With free-burning bituminous	75 feet
With anthracite of medium and large size	100 feet
With slow-burning bituminous	120 feet
With anthracite pea	130 feet
With anthracite buckwheat	150 feet
With anthracite slack	175 feet

For plants of 700 or 800 horse-power or over, the chimney should not be less than 150 feet high regardless of the kind of coal used. It is evident that the figures in the above table are subject to wide variations with different qualities of coal as regards caking and non-caking, clinkering and non-clinkering, etc., with different proportions of grate to heating surface and with different kinds of grates and furnaces.

On account of the elimination of the grate in oil-burning boilers and the injection of oil under pressure the height of a chimney for an oil-burning boiler is less than for a coal-burning boiler of the same capacity. According to Gebhardt a height of from 80 to 90 feet is sufficient to force oil-burning boilers to 50 per cent above their rating. In large oil-burning plants, however, the chimney is usually designed on the coal-burning basis, in order to permit the use of coal should this subsequently prove desirable.

CROSS SECTION OF CHIMNEY.—When the height of the chimney has been decided upon, the proper cross section may be determined as follows: Let

C = pounds of coal to be burned per hour,
H = height of chimney in feet,
A = internal cross section of chimney in square feet,
D = internal diameter of chimney, if round, in inches,
S = side, internal, of chimney, if square, in inches,
E = "effective" internal cross section in square feet,
P = total rated boiler horse-power.

Then

$$E = \frac{3C}{50\sqrt{H}}, \qquad D = 13.54\sqrt{E} + 4, \qquad S = 12\sqrt{E} + 4,$$

$$A = 0.0546\,D^2 = \frac{S^2}{144}.$$

Allowing 5 pounds of coal per rated boiler horse-power per hour the formula for E may be written

$$E = \frac{3P}{10\sqrt{H}}.$$

Five pounds of coal per boiler horse-power per hour is a liberal allowance to cover the contingencies of poor coal being used, and of the boilers being driven beyond their rated capacity. In large plants with economical boilers, good fuel and other favorable conditions, the maximum rate of coal consumption will be considerably less than 5 pounds (*see Boilers*). Calling R

the maximum rate of coal consumption in pounds per hour per rated boiler horse-power, the formula for E may be written

$$E = \frac{3\,RP}{50\sqrt{H}}.$$

STABILITY — THICKNESS OF WALLS. — All chimneys of any considerable size should consist of an outer stack of sufficient strength to give stability to the structure, and an inner stack or core, independent of the outer one, to protect the latter from the high temperature of the hot gases. This core sometimes extends up to a height of but 50 or 60 feet above the base of the chimney, but better practice is to extend it the full height or to 100 to 120 feet in chimneys over 120 feet high. The core is usually constructed of fire brick; the outer stack may be built of common brick or radial brick (the Custodis chimney is an example of the latter) or of steel or of reinforced concrete. To determine whether a chimney is stable, treat it as a cantilever loaded throughout its length with a load equal to the total pressure (*see Elasticity and Strength; Wind Pressure*); at no section of the chimney should the stress in the walls exceed the safe working stress for the material of which it is constructed.

Brick Chimneys. — A general rule for diameter of base of brick chimneys, approved by many years of practice in England and the United States, is to make the diameter of the base one-tenth of the height. If the chimney is square or rectangular, make the diameter of the inscribed circle of the base one-tenth of the height. The "batter" or taper of a chimney should be from 1/16 to 1/4 inch to the foot on each side. The brickwork should be one brick (8 or 9 inches) thick for the first 25 feet from the top, increasing 1/2 brick (4 or 4 1/2 inches) for each 25 feet from the top downwards. If the inside diameter exceeds 5 feet, the top length should be 1 1/2 bricks and if under 3 feet, it may be 1/2 brick for 10 feet.

Reinforced Concrete Chimneys began to come into extensive use in this country in 1901 and several hundred of them are now in use. Reinforced concrete chimneys built by the Weber Co., of Chicago, consist of two parts, the lower double shell and the single shell above. The inside shell is usually 4 inches thick, while the thickness of the outside shell depends upon the height and varies from 6 to 12 inches. The single shell is from 4 to 10 inches thick. The height of the double shell depends upon the height of the chimney, nature and temperature of the gases, etc. The bending forces caused by wind pressure are taken up by vertical steel reinforcement; the resistance of the concrete itself against tension is not considered in calculation.

Steel Chimneys are largely used, especially for tall chimneys of iron-works, from 150 to 300 feet in height. The advantages claimed are: greater strength and safety; smaller space required; smaller cost, by 30 to 50 per cent, as compared with brick chimneys; avoidance of infiltration of air and consequent checking of the draft, common in brick chimneys. They are usually made cylindrical in shape, with a wide-curved flare for 10 to 25 feet at the bottom. A heavy cast-iron base-plate is provided, to which the chimney is riveted, and the plate is secured to a massive foundation by holding-down bolts. No guys are used.

Sheet-iron Smokestacks are relatively cheap in first cost, but depreciate rapidly. A heavy foundation is not necessary, but the stack may be supported directly on the boiler breeching. The stacks are not self-supporting but must be held upright by guy wires.

WEIGHT OF SHEET-IRON SMOKESTACKS PER FOOT (Porter Mfg. Co.)

Diam., in.	Thickness, W.G.	Lb. per ft.	Diam. in.	Thickness, W.G.	Lb. per ft.	Diam., in.	Thickness, W.G.	Lb. per ft.
10	No. 16	7.20	26	No. 16	17.50	20	No. 14	18.33

20	"	13.75	12	"	11.11	28	"	25.00
22	"	15.00	14	"	13.69	30	"	26.66
24	"	16.25	16	"	15.00	...	.....	.....

FOUNDATIONS. — Chimney foundations are as a rule constructed of concrete except where the nature of the soil necessitates the use of piles or a grillage of timber or steel. (For the bearing power of various soils see section on *Foundations* in article on *Power Stations*.) For masonry chimneys the foundation is designed to give the necessary support for the shaft without particular reference to its weight and shape. In steel and reinforced concrete chimneys the weight and shape of the foundation are important factors in securing the proper stability of the chimney, since the shaft is usually securely fastened to the foundation and the two form practically one mass.

SIZES OF FOUNDATIONS FOR HALF-LINED STEEL CHIMNEYS
(Selected from circular of Phila. Engineering Works.)

Diameter, clear, feet	3	4	5	6	7	9	11
Height, feet	100	100	150	150	150	150	150
Least diam. foundation, ft. and in.	15–9	16–4	20–4	21–10	22–7	23–8	24–8
Least depth foundation, feet	6	6	9	8	9	10	10
Height, feet	.....	125	200	200	250	275	300
Least diam. foundation, ft. and in.	.....	18–5	23–8	25	29–8	33–6	36
Least depth foundation, feet	.....	7	10	10	12	12	14

BREECHING. — The area of the flue or breeching leading from the boilers to the stack is usually made 20 per cent greater than that of the stack. When several boilers discharge into the same flue its section may be tapered and proportioned to the number of boilers. When two flues enter the stack on opposite sides at the same level a diaphragm is inserted between the two openings.

COSTS. — The cost of chimneys in large power stations ranges from $1.85 to $2.50 per rated boiler horse-power. Christie (*Chimney Design and Theory*) gives the following costs of chimneys 150 feet high and 8 feet internal diameter.

Common red brick	$8500
Radial brick	6800
Steel, self-supporting, full lined	8300
Steel, self-supporting, half lined	7800
Steel, self-supporting, unlined	5800
Steel, guyed	4000

The following approximate cost of radial brick chimneys (adapted from Gebhardt, *Steam Power Plant Engineering*) will serve to indicate the variation in cost with height and diameter:

COST OF RADIAL BRICK CHIMNEYS

Diameter in feet	Height in feet					
	75	125	150	175	200	250
4	$1400	$3500	.....	.....	.....	.....
6	2000	4300	.....	.....	.....	.....
8	2700	4700	$6200	$7100	$9,300	.....
10	3700	5100	7100	7900	10,500	$16,500
12	.....	.....	7800	9000	11,100	18,300
14	.....	.....	8300	9700	12,500	21,500
16	.....	.....	.....	.....	.....	24,300

Sheet-iron smokestacks cost from 3.5 to 6.5 cents per pound, the higher unit price referring to the smaller sizes.

Brick and concrete stacks involve little expense for maintenance, 2 per cent being a liberal allowance for both maintenance and depreciation. Steel and sheet-iron stacks require occasional painting to prevent excessive corrosion.

[Wm. Kent.]

CIRCUIT BREAKERS. — (*See also Bus-Bars; Switchboards; Switches; Switchgear Equipment for Power Stations.*) A circuit breaker is a device to open an electric circuit which is normally held closed by the action of a latch, toggle or similar mechanism. This tendency to open is the feature that usually distinguishes a circuit breaker from a switch, as the latter, although used to open electric circuits, is without any latch or similar device and hence will remain in the closed position. This distinction between switches and circuit breakers is not always followed, as circuit breakers which open in oil are frequently spoken of as "oil switches."

TYPES OF CIRCUIT BREAKERS. — When a circuit breaker automatically opens the circuit as the result of certain abnormal conditions, such as overload, the circuit breaker is said to be "automatic," but if the breaker does not open unless tripped by the attendant it is spoken of as "non-automatic." An automatic breaker usually can be released by hand also. A breaker designed to be closed directly by the operator is spoken of as "direct controlled," while a breaker mounted at a distance is "remote controlled," The latter can be "hand operated" if worked through a system of bell cranks, levers or similar devices; "electrically operated" if worked by motor or solenoid; or "pneumatically operated" if controlled by compressed air.

Small circuit breakers, particularly of low voltage, are usually direct controlled, and large-capacity high-voltage breakers are usually remote controlled, some auxiliary source of power being employed. For such distant-controlled breakers automatic operation is secured through relays (*see Relays*). Relays are also frequently used with direct-controlled breakers.

Underload, Over-voltage, Under-voltage and Reverse Current Breakers. — The principal demand for circuit breakers is to have them open the circuit when the current reaches a certain predetermined value, and breakers are designed with this end in view. They are also built for underload conditions to open on minimum current, for over-voltage to open when the voltage exceeds a certain amount, for under-voltage to open when the voltage falls below a certain minimum value, for reversal when the current flows in the opposite direction through the breaker from that which was intended. It is, of course, possible to combine these various features of overload, underload, reversal, etc., in one and the same breaker. (*See Relays.*)

PRINCIPLE OF OPERATION. — The opening of a circuit breaker is usually secured by the releasing of a latch or the upsetting of a toggle joint that keeps the breaker closed. Various schemes have been adopted to secure the adjustment or "calibration" of the overload tripping device, so that it may be made to operate within reasonably wide limits, usually 80 to 160 per cent of the normal rating.

Breakers Opening in Air. — Fig. 1 shows the general arrangement of the magnetic circuit of a typical carbon-break circuit breaker, arranged for hand or solenoid operation, as used on heavy-capacity d-c. and low-voltage a-c. circuits. The current passes in at one stud across the contact brush and back through the other stud, thus forming a loop or turn in the electric circuit. A U-shaped iron frame is placed around the lower stud and the movable armature completes the magnetic circuit.

The current passing through the breaker magnetizes the iron circuit and tends to lift the movable armature. At a certain predetermined current the attraction overcomes the force of gravity, and the raising of the moving arm opens the latch or upsets the toggle which holds the breaker closed.

Two methods of securing the necessary range or calibration can be employed, one by varying the air gap between the stationary and moving iron, and the

other by giving the electromagnet more work to do by increasing the weight to be lifted. This latter method can employ either additional weights at a fixed

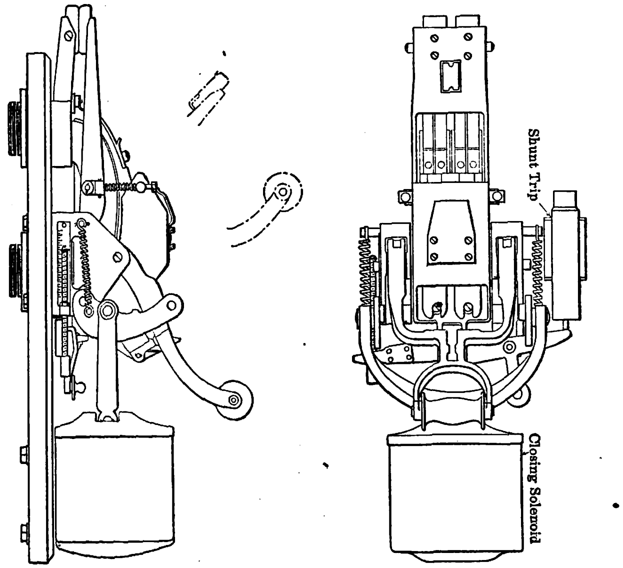

Fig. 1. Carbon-break Circuit Breaker

distance from the fulcrum, or a fixed weight at a variable distance from the fulcrum.

For small currents the electrical circuit is carried more than once around the iron circuit, which results in a solenoid design with a movable plunger. With this scheme the tripping range is secured by adding weights to the solenoid or varying the air gap.

Oil Circuit Breakers (Figs. 2 to 6). — With high-voltage oil circuit breakers the tripping coil is usually a solenoid of a fairly large number of turns, which is connected in series with the main circuit or serves as the secondary of a current transformer whose primary is connected in the high-tension circuit. For polyphase circuits two or more tripping coils are used.

DESIGN. — For different classes of service various types of circuit breakers are used, and the functions of these types overlap more or less. The following table gives the approximate values of the maximum normal current and voltage for which these various types are used at present.

In connection with the carbon-break circuit breaker 24,000 amperes is the largest size in actual service, but larger breakers could be built if desired. 2400 volts is the maximum d-c. voltage at present used for railway service in America, but carbon breakers can be built for higher d-c. voltages if desired; they have been used up to 22,000 volts for a-c. service.

The fuse type has not been built for more than 100 amperes or 66,000 volts, but could be made for higher voltages if desired.

Type	Maximum current, amperes	Maximum voltage
Carbon break	24,000	2,400
Fuse type	100	66,000
Magnetic blow-out	10,000	750
Oil break	4,000	150,000

The magnetic blow-out type has been built in capacities up to 10,000 amperes for d-c. railway service, but in large sizes has been practically superseded by the carbon break.

The oil-break type is in service for capacities up to 4000 amperes and for voltages up to 150,000, but designs have been made for larger currents and higher voltages and these can be supplied to meet whatever demand may exist.

Air-break Carbon-type Breakers are made in a variety of designs; Fig. 1 shows a typical single-pole carbon-break circuit breaker. As shown in the figure, the circuit-breaker mechanism consists of a swinging arm carrying the main and the arcing contacts actuated by a handle and toggle-joint mechanism. The main contacts are of copper and are laminated to insure a perfect contact with the copper blocks which are fastened to the base and connected to the line. Above the copper contacts are the arcing contacts of carbon. These contacts consist of one or more carbons carried by a swinging arm and pressed firmly against stationary contacts when the breaker is closed. These carbons are mounted on a pivot to insure proper adjustment.

When the breaker opens the current is gradually shifted through the copper shunts to the carbon contacts, and thus no arc is formed until the final break takes place between the carbon contacts at the top. This arrangement, combined with the natural tendency of an arc to rise, prevents any injury to the breaker by the arc.

Heavy-capacity carbon-break circuit breakers are also made motor-operated, in which case the breaker has a device that disconnects the worm gear and shuts down the motor when the breaker has closed and its toggle has locked. It is also so arranged that if an overload or short-circuit exists when the breaker is closed, the breaker will immediately trip out even though the control switch is held in the "close" position. This feature of being "nonclosable on overload" is one that is embodied in a large number of breakers of all kinds, and is a very valuable and useful one.

Switch and Breaker for Rotary Converters. — A combination motor-operated switch and circuit breaker has been supplied for various rotary converters and 600-volt feeder circuits supplying current for third-rail electrifications. One motor is provided for each combined circuit breaker and switch, and it has suitable clutches, shafts, operating rods and mechanism, so that in the act of closing the circuit breaker is first thrown in and the closing device is then disconnected before the swtich is thrown in, so that in case of trouble the breaker can immediately trip out and open the circuit.

Air-break Fuse-type Breaker. — This type is a modification of the carbon-break type and is intended for moderate capacity circuits for voltages of 6000 to 60,000. This breaker consists essentially of a stationary and a movable arm mounted on suitable insulators supporting the line connections. These arms are hinged together at one end. The free ends are held together ...

a strong spring by a piece of aluminum fuse wire that passes through a blow-out tube. When the current exceeds a certain amount, the fuse wire melts and the free end of the movable arm swings away from the stationary arm, the arc being ruptured in a blow-out tube.

Magnetic Blow-out Type Breaker.—This type of breaker is provided with auxiliary contacts that open in a strong magnetic field which blows out the arc formed at these auxiliary contacts. The main contacts are solid copper blocks bridged by a laminated copper brush. These open first when the breaker operates, leaving the final arc to be broken on the auxiliary contacts, which are protected by the magnetic blow-out device and which can be readily renewed at comparatively small expense. Although breakers of this type have been installed on the switchboards of power plants, they have been practically superseded by carbon breakers for this work. For such service as the protection of the circuits on a railway car, requiring a few hundred amperes at 600 volts, the magnetic blow-out principle is used to advantage, as the discharge vent from the blow-out compartment can be so set that the vapors from the arc will do no damage.

Oil Circuit Breaker (Figs. 2 to 6).—The essential feature of this type of breaker is the opening of the circuit under oil and the smothering of the arc in a restricted space. These breakers are used almost to the exclusion of all other designs on a-c. circuits of large capacity and high voltage. Oscillograph tests show that the circuit is interrupted at the time of zero point of the alternating-current wave, and, therefore, there is little tendency to set up surges in the circuit. The rapid interruption of a direct current, however, is apt to set up surges, and therefore the oil-break design is not commonly used with d-c. service.

Oil-break circuit breakers are designed to meet various conditions of current, voltage and amount of power that they might be called upon to handle in case of a short-circuit. For moderate amounts of power where the size and cost of the breaker is to be kept to a minimum it is often possible to locate all the poles in one oil tank. For slightly larger amounts of power each pole is in a separate oil tank but all the poles are mounted on the same frame. For still greater amounts of power at moderate voltages each pole is in a separate tank and each tank in a separate compartment. For very high-voltage work each pole is in a separate steel tank of such substantial construction as to be proof against any explosion due to the effects of a short-circuit.

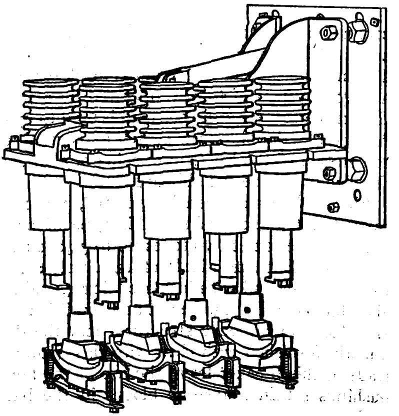

Fig. 2. 300-ampere, 15,000-volt, 4-pole Circuit Breaker

Fig. 2 shows a 300-ampere, 15,000-volt, 4-pole breaker. This type is built in capacities up to 2000 amperes at 600 volts, and up to 200 amperes at 22,000 volts. In this type of breaker each pair of contacts forming each pole is in a separate tank with insulating lining. This breaker is readily arranged for hand operation or electrical operation, can be

mounted on a wall, framework, switchboard panel, or on suitable supports, and may be placed in a masonry structure if desired.

Fig. 3 shows a solenoid-operated breaker of a design that is built in single-pole units in capacities up to 4000 amperes at 600 volts, and 100 amperes at 33,000 volts. Each pole of the breaker is intended for mounting in a masonry

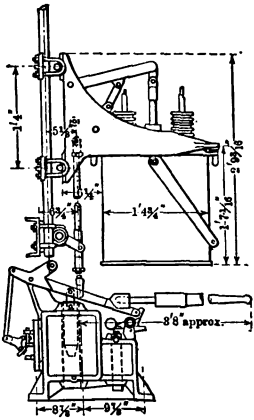

Fig. 3. 300-ampere, 15,000-volt, Solenoid Operated, Wall Mounting Oil Circuit Breaker

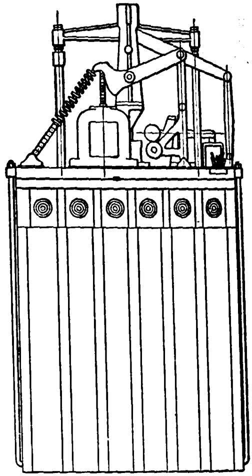

Fig. 4. Three-pole, Solenoid Operated, 13,200-volt, Oil Circuit Breaker

compartment, or on a framework, and 2-, 3-, or 4-pole units are made by connecting the mechanisms of 2, 3, or 4 poles to the same solenoid operating system. The mechanism and the terminal insulators are mounted on a suitable base and a simple system of toggles operated by a powerful solenoid is used for closing the breakers. A second solenoid is used to upset the toggle and trip the breaker. A two-pole, double-throw switch is mounted on the breaker and is operated by the motion of the levers in opening or closing the breaker; this switch controls the signals on the switchboard.

Fig. 4 shows a solenoid-operated, top-connected breaker of 600 amperes capacity at 13,200 volts. This type of breaker is built in capacities up to 3000 amperes and in voltages up to 33,000 and is used in stations of the largest capacity. Both terminals of each pole are in a single oval steel tank with welded seams and with insulated lining, and each tank is provided with a gauge glass for observing the height and condition of the oil. The breakers in service are placed in masonry structures and the doors of the compartment are frequently furnished with clear wire-glass panes to permit ready inspection. The leads of this breaker leave the top of the tank and pass out through porcelain bushings set in soapstone blocks in the back wall of the structure. These leads usually come out in separate compartments that keep them isolated from each other. The leads to the bus-bars, feeders, generators, etc., may all run upward or all downward, or some of them up and some down.

Fig. 5 shows one element and the controlling device for an 88,000-volt, 3-pole, 300-ampere breaker arranged for distant electrical control. Each pole of the

breaker is located in a welded steel tank with treated lining. All its mechanism is mounted complete on its cast-iron top. A 3-pole breaker is made up of three such elements, entirely independent of each other except that they are connected by a single operating rod. The spacing of the poles can thus be made to suit the station wiring. For mechanical operation the solenoid is replaced by a bell-crank device. The condenser bushing leads that form the stationary terminals can readily be unclamped and removed through the cover. The series transformers for the operation of ammeters and relays are clamped directly around the condenser bushing leads, which form the single-turn primary. This permits the use of a simple, compact, and cheap form of series transformer.

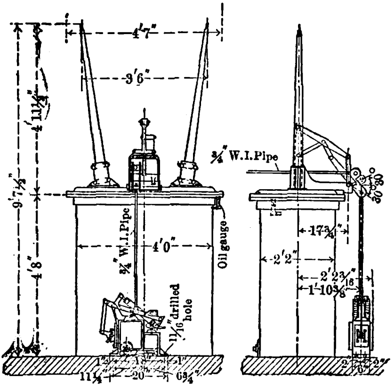

Fig. 5. Solenoid Operated, 88,000-volt, Oil Circuit Breaker, Indoor Type

Fig. 6 shows the corresponding 88,000-volt electrically-operated breaker intended for outdoor service. Its main features correspond closely with those in Fig. 5 previously described. For outdoor service the condenser-bushing leads of the breaker are covered with a series of porcelain insulators and the space between the bushing and the insulators is filled with a moistureproof compound. The operating mechanism is covered by a metallic hood and the pull rods connecting the poles of the breakers pass through pipes. The various joints are made thoroughly waterproof. Outdoor breakers of this design have been operating very satisfactorily on the lines of the Dominion Power and Transmission Co., near Hamilton, Ontario; the Niagara, Lockport and Ontario Power Co.'s lines near Niagara Falls, New York; and the Southern Power Company's circuits, and other plants.

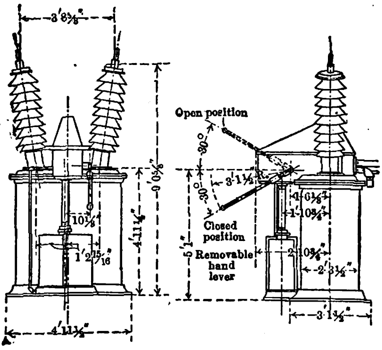

Fig. 6. Solenoid Operated, 88,000-volt, Oil Circuit Breaker, Outdoor Type

RATING — (*See below for Table of Sizes.*) The rating of a circuit breaker is usually given as the normal current which it will carry continuously with a temperature rise not exceeding 28° C. for carbon breakers and 50° C. for oil breakers, above the surrounding air. This rating has no direct relation to the maximum short-circuit current which the breaker will safely interrupt. (*See below under Ultimate Capacity.*) The tripping range of the breaker is usually

from 80 to 160 per cent of this normal rating. The cross-section of the conductors and the area of contact surfaces depend so much upon the character of design, the cooling effect of bodies of oil and masses of metal, that no definite current density can be given as an average value for the various types of breakers.

Ultimate Breaking Capacity. — (*See table below.*) When a short circuit or ground occurs on a line, the rush of current thereby produced depends upon: (1) the total resistance and reactance of all parts of the circuit through which flows this current or other currents induced thereby, (2) the demagnetizing action of these currents on the fields of the generators producing them, and (3) the lag of this demagnetizing action behind the current producing it. The ability of a breaker to interrupt, without damage to itself, a current of a given magnitude depends upon various features of design, and it is evidently impossible to state how much synchronous or transforming apparatus may be safely connected directly to a breaker of a given rating, unless the conditions of operation are also fully specified. In the table below the "ultimate capacity" of various breakers is given in terms of the total capacity of synchronous apparatus, in normal kilovolt-amperes, which may feed directly into a short circuit through the given breaker when provided with an instantaneous release without causing damage to the breaker upon opening. The breakers are considered to be connected with no other reactance in the circuit than the inherent reactance of the synchronous apparatus assumed as 8 per cent.

Effect of Circuit Characteristics on Ultimate Capacity. — The ultimate kilovolt-ampere capacity of the breakers given in the table below would be approximately as follows under the conditions stated.

Ultimate capacity for any other reactance in the circuit increases directly in proportion to the total reactance.

When a breaker is separated from all sources of energy by one or more transformers which have a total kilovolt-ampere rating very much less than the kilovolt-ampere rating of the generators, the kilovolt-ampere capacity of the breaker need not be greater than the kilovolt-ampere rating of these transformers, provided their reactance is not less than 8 per cent. When a breaker is provided with a time-limit overload release of 2 seconds or more, its capacity in kilovolt-amperes will be approximately twice that given in the table.

When a breaker is used on a circuit of lower voltage than that for which it is designed, the kilovolt-ampere capacity of the breaker will be increased in the ratio of the voltage decrease. Most careful consideration should be given the relation of breakers to other apparatus and bus bars with the view of minimizing the risk of danger from the expulsion of inflammable gases, realizing that the risk increases as circuit voltage and station capacity increase.

INSTALLATION. — Carbon-break circuit breakers are usually mounted at the top of a switchboard panel and ample head room is provided to prevent an arc from causing damage. Magnetic blow-out breakers, when placed on a switchboard, are usually located at the top for similar reasons. Fused circuit breakers are usually placed on the station wall or a framework with ample space around them. Oil circuit breakers of the smaller sizes can be mounted directly on the rear of a switchboard panel or on an auxiliary framework or in masonry compartments. The larger capacity breakers are almost invariably placed with each pole in a separate masonry compartment. The very high voltage breakers are mounted in the open.

DIMENSIONS, WEIGHTS AND COSTS. — Although the dimensions, weights, costs, etc., of breakers of various manufacturers naturally differ and the same manufacturer frequently builds various grades for the same capacity, the information given below will be an approximate guide for breakers made by

The dimensions of height, breadth and depth for carbon breakers refer to the switchboard mounting. The depth is given from the front of the panel, i.e., the length of the studs projecting through the panel is neglected. With the oil-break types for switchboard mounting the dimensions are from the back of the panel, i.e., the length of handle sticking through the board is neglected. For the wall-mounted circuit breakers the dimensions include the cells although the weights and prices do not. For the high-voltage breakers the dimensions are for the minimum spacing recommended for any particular voltage. The dimensions are in every case the maximum over-all dimensions except as mentioned.

The costs given below are the approximate selling prices at the time of the preparation of this handbook (1913) and are sufficiently accurate for the preparation of preliminary estimates, but for accurate work should be checked by actual quotations from a reliable builder.

RATING, ULTIMATE CAPACITY, DIMENSIONS, WEIGHTS AND COSTS

Mark	Amperes	Volts	Ultimate capacity, kv-a.	Height, inches	Width, inches	Depth, inches	Weight, pounds	Prices, dollars

[S. Q. HAYES.]

COLLECTORS, CURRENT. — (*See also Cars, Electric; Locomotives, Electric; Third-Rail Systems; Trolley Systems, Overhead; Trolley Systems, Underground.*) Current collectors for electric cars or locomotives are divided into three classes in accordance with the form of the working conductor from which they collect current, as follows:

(*a*) Overhead Trolley, which may be of the wheel, scraping bow or roller type.

(*b*) Third-Rail Shoes, which may be of the over-running or under-running type.

(*c*) Underground Conduit Plow.

WHEEL TROLLEY. — The wheel trolley consists of a grooved brass or copper wheel held in bearings in a prong called a "harp" at the end of a steel pole which is pressed upward by a system of springs and levers. The trolley wire is from 18 to 22 feet above the rails. The pole presses the wheel upward against the wire with a pressure of from 20 to 40 pounds, the higher pressure being used for the higher speeds. For single cars requiring a current less than 200 amperes at full speed this type of current collector is most satisfactory. The current which it can collect is limited at the various speeds as indicated in the accompanying table. If greater currents are required, resort must be had to the third rail. The trolley wheel is not very satisfactory on cars in trains as each trolley pole requires the attention of a conductor to replace it at curves and switches, and moreover, it is difficult to manipulate the trolley pole from a platform between two cars.

Miles per hour	Amperes
5	1200
15	600
40	350
60	200

BOW OR SCRAPER TROLLEY. — This type of trolley is used to collect current from a high-voltage conductor because it is self-adjusting and needs no attention. At high voltages its current capacity, limited at high speeds to about 100 amperes, is sufficient to supply power for a train of considerable size but it would not have sufficient capacity to supply power for heavy trains at 600 volts. The bow may be held up either by simple springs in the same manner as the trolley pole or it may be mounted upon a pantagraph mechanism which is held up by springs and folded down by a compressed-air cylinder. A special form of overhead construction must be used for the bow trolley as the bow would strike the downwardly projecting ears and the guy wires of the ordinary trolley construction. The roller trolley may be used in place of the bow on the same form of mechanism. The roller has a greater current capacity and causes less wear on the working conductor than the bow.

THIRD-RAIL SHOES. — A third rail will collect currents as high as 2000 amperes at low speeds and 600 amperes at 60 miles per hour. As they are self-adjusting two or three may be placed on a locomotive or car just as well as one, so that there is practically no limit to the current that can be collected in this way. In fact it is always customary to put two on each side of each locomotive or car in order to prevent a cessation of current when passing over breaks in the third rail due to switches or crossings. The relative position of the third rail with respect to the running rails is a very important matter which has not been thoroughly standardized as yet, but has been the subject of much discussion. It must be placed so that all the rolling stock on the road will clear it.

Over-running vs. Under-running Types. — The third rail for top contact or for over-running shoe is cheaper to install, to protect and to maintain and is most generally used. The under-contact rail is less liable to trouble from sleet,

UNDERGROUND CONDUIT PLOW. — The underground plow consists of an insulated steel plate hung from a movable structure on the car. On the two sides of this plate and thoroughly insulated from it are two shoes pressed outward from the plate by springs. These shoes press against the two working conductors which are usually steel Tees separated from each other by about 6 inches and supported on some form of ceramic insulator. The current is led from the shoes to the car body by flexible insulated conductors.

[W. I. SLICHTER.]

COMPLEX QUANTITIES. — (*See also Vectors.*) The square root of a negative quantity is called an "imaginary" quantity, or a pure imaginary. A quantity consisting of the sum or difference of a real quantity and an imaginary quantity is called a "complex" quantity. For example, $\sqrt{-3}$ is a pure imaginary, and $2+\sqrt{-3}$ is a complex quantity. All the rules of ordinary algebra apply to pure imaginaries and complex quantities. For example, $\sqrt{-3}$ may be written $\sqrt{-1}\sqrt{3}$, and in general $\sqrt{-a}$, where a is a positive quantity, may be written $\sqrt{-1}\sqrt{a}$. The square root of minus one is called the imaginary unit and is usually represented by the symbol j (writers on pure mathematics use the symbol i), that is,

$$j=\sqrt{-1}.$$

Any complex quantity may then be written

$$a+jb,$$

where a and b are both real quantities.

Geometrical Representation of a Complex Quantity. — A positive real quantity may be represented by a line drawn in a given direction; a negative real quantity may be represented by a line drawn in the opposite direction. Multiplying a quantity by -1 then reverses its direction. Also, since multiplying a real quantity by $\sqrt{-1}$ twice is equivalent to multiplying it by -1, the operation of multiplying once by $\sqrt{-1}$ may be represented by turning the line representing the quantity through 90° in the positive direction of rotation. The positive direction of rotation is taken as the opposite direction to that in which the hands of a clock move. Hence, a complex quantity $a+jb$ may be represented by the line OP in the figure, where $OA=a$ and $AP=b$. The complex quantity $a+jb$ is then completely specified by a line of length $\sqrt{a^2+b^2}$ making an angle θ, with the axis of reference OX where $\tan\theta=\frac{b}{a}$.

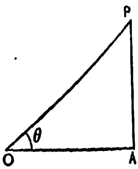

Fig. 1

The length $M=\sqrt{a^2+b^2}$ is called the magnitude of the complex quantity and the angle $\theta=\tan^{-1}\frac{b}{a}$ is called its angle. From the figure it is evident that the complex quantity $a+jb$ may also be written

$$a+jb=M(\cos\theta+j\sin\theta).$$

Expanding $\cos\theta$ and $\sin\theta$ into series (*see Series*) and adding, the resultant series obtained is the series for $\epsilon^{j\theta}$; hence

$$a+jb=M\epsilon^{j\theta}. \qquad (1)$$

From the above definitions and equation (1) it is evident that complex numbers possess the following properties:

Addition of Two Complex Quantities. —

$$(a+jb)+(a_1+jb_1)=(a+a_1)+j(b+b_1).$$

Subtraction of Two Complex Quantities. —

$$(a+jb)-(a_1+jb_1)=(a-a_1)+j(b-b_1).$$

Multiplication of a Complex Quantity by a Complex Number. —

$$(a+jb)\,(a_1+jb_1) = aa_1 - bb_1 + j\,(ab_1 + a_1b)$$

or, putting $a+jb = M\epsilon^{j\theta}$ and $a_1+jb_1 = M_1\epsilon^{j\theta_1}$

where $M = \sqrt{a^2+b^2}$, $M_1 = \sqrt{a_1{}^2+b_1{}^2}$,

$$\tan\theta = \frac{b}{a},$$

and

$$\tan\theta_1 = \frac{b_1}{a_1}$$

we have $(a+jb)\,(a_1+jb_1) = M\epsilon^{j\theta}M_1\epsilon^{j\theta_1} = MM_1\epsilon^{j(\theta+\theta_1)}.$

Hence the product of two complex quantities is in general a complex quantity which has a magnitude equal to the product of the magnitudes of the two quantities and an angle equal to the sum of the angles of the two quantities.

Division of a Complex Quantity by a Complex Number. —

$$\frac{a+jb}{a_1+jb_1} = \frac{(a+jb)(a_1-jb_1)}{(a_1+jb_1)(a_1-jb_1)} = \frac{aa_1+bb_1-j\,(ab_1-a_1b)}{a_1{}^2+b_1{}^2}$$

or

$$\frac{a+jb}{a_1+jb_1} = \frac{M\epsilon^{j\theta}}{M_1\epsilon^{j\theta_1}} = \frac{M}{M_1}\,\epsilon^{j(\theta-\theta_1)}.$$

Hence the quotient of two complex quantities is in general a complex quantity which has a magnitude equal to the quotient of the magnitudes of the two quantities and an angle equal to the difference of the angles of the two quantities.

Example. — Suppose

$$I = \frac{10+j\,15}{3+j\,1};$$

then by the rule for division

$$I = 4.5 + j\,3.5,$$

that is, I contains a real part 4.5 and an imaginary part j 3.5.

Equations Containing Complex Quantities. — Since a real quantity cannot be equal to an imaginary quantity it follows that any equation of the form

$$A+jB = A_1+jB_1,$$

where A, B, A_1 and B_1 are all real quantities (which may, however, consist of any number of terms), is equivalent to the two equations

$$A = A_1$$

and

$$B = B_1.$$

Also, if one member of an equation reduces to the form $A+jB$, then the other member of this equation must likewise contain an equal real and an equal imaginary part.

[W. A. Del Mar.]

CONCRETE. — (*See also Cement; Concrete, Reinforced.*) Concrete as used by engineers in construction is generally formed of an artificial mixture of Portland cement (*see Cement*) and an aggregate consisting of sand and gravel or broken stone. These ingredients are mixed with water either by hand or by machine mixers. When in a semi-liquid form the material can be shoveled or poured into molds, and will gradually harden in either air or water, forming an artificial stone of high strength. The compressive strength of concrete varies with the quality and proportion of the materials; the tensile strength is very low and is usually neglected.

SPECIFICATIONS. — The quality of the materials can be determined only by careful tests, but for construction of minor importance and magnitude the following simple specifications should give good results.

Cement. — The cement shall be first-class American Portland cement of standard brand, guaranteed to conform to the Standard Specifications of the American Society for Testing Materials. (*See Cement.*) Such cement may be delivered either in bags or barrels but must be kept dry during storage.

Sand. — The sand shall be clean and coarse and free from dust, vegetable, loam or other organic matter, and other impurities, and should pass, when dry, a screen with holes $\frac{1}{4}$ of an inch in diameter.

Gravel. — The gravel shall consist of clean pebbles, and contain no foreign matter. It shall be screened over a $\frac{1}{4}$-inch mesh; the sand passing through the screen may be remixed in definite proportions with the gravel. If dirty or clayey, the gravel should be washed by a hose before mixing.

Broken Stone. — The broken stone shall consist of hard and durable stone such as trap, granite and limestone. Unless otherwise specified, all stone shall pass through a $2\frac{1}{2}$-inch screen.

Water. — The water used for mixing shall be free from oil, acid and other injurious substances.

PROPORTION OF INGREDIENTS. — The amount of each ingredient is usually measured by volume. The concrete is designated by the proportion by volume of each of the ingredients in the following order: Cement, Sand, Stone or Gravel. For example, a 1 : 2 : 4 mixture is one consisting of one barrel of cement, two barrels of coarse sand, and four barrels of loose gravel or broken stone (standard cement barrels contain 3.8 cu. ft; four bags of packed cement may be considered as equal to one barrel).

The following proportions are somewhat generally adopted for different classes of work.

1:1:2 or $1:1\frac{1}{2}:3$ for water tanks and standpipes carrying considerable pressure and required to be water-tight.

1:2:4 for arches, reinforced floors, beams, columns, engine foundations subject to vibration, sewers, and in general for structures subjected to bending stresses of some magnitude. A mixture as rich as this is also desirable where concrete is to be deposited under water since in such a case some of the cement may be washed away from the mixture.

$1:2\frac{1}{2}:5$ for bridge abutments and piers when laid in air, retaining walls and ordinary machine foundations.

1:3:6 for heavy walls, ordinary foundations, backing for stone masonry, etc.

Quantity of Ingredients.— The following rule devised by Wm. B. Fuller may be used for approximate determination of the quantity of the various ingredients.

Let c = number of parts of cement,
s = number of parts of sand,
g = number of parts of gravel or broken stone,

then $\dfrac{11}{c+s+g} = N$ = number of barrels of Portland cement required per cu. yd. of concrete,

$N \times s \times \dfrac{3.8}{27}$ = number of cu. yd. of sand required for one cu. yd. of concrete,

$N \times g \times \dfrac{3.8}{27}$ = number of cu. yd. of stone or gravel required for one cu. yd. of concrete.

For tables giving more accurate values see **Taylor and Thompson**, *Concrete Costs*, N. Y., 1912.

MIXING. — The ingredients consisting of sand and aggregate should be thoroughly mixed while dry until the mass is uniform in color and homogeneous. Mixing should preferably be done by machine. When necessary to mix by hand, the mixing should be done on a water-tight platform and the ingredients should be turned not less than six times. Enough water should be used to produce a mixture which will flow readily into its place in forms or elsewhere.

Concrete Mixing in Freezing Weather. — Reinforced concrete should not be mixed or deposited in freezing weather unless special precautions are taken to keep the materials free from ice, and to protect the concrete from freezing until it has been thoroughly hardened. To accomplish these results the aggregate may be heated, salt water used in mixing, and the concrete carefully covered after it has been deposited. Portland cement concrete which is to be deposited in large masses may be laid in freezing weather provided the surface appearance is not important, and provided that hardened surfaces be thoroughly cleaned from frost as well as dirt before a new surface is laid. Natural cement concrete should never be laid in freezing weather.

Concrete Shrinkage and Temperature Changes. — Cracks in cement may be caused by contraction in setting, or by temperature changes, as well as by excessive stress. To preserve a good appearance it is common to establish artificial cracks in long walls, sidewalks, etc. For spacing of such cracks see reference in *Bibliography*. The insertion of steel reinforcing bars even when not needed to carry stresses due to applied loads is an expedient often adopted to prevent the occurrence of such cracks. The amount of reinforcement to be used for this purpose should generally be not less than one-third of one per cent.

Effect of Sea Water and of Acids on Concrete. — The data available relating to the effect of sea water upon concrete indicate that there may be some chemical action resulting in a softening and disintegration of the surface; to offset this action as far as possible, concrete laid in sea water should be carefully proportioned and well mixed. There is also great danger from disintegration due to frost in cold climates in concrete lying between high water and low water. To protect against this the concrete may be protected by a surface of stone in the zone exposed to such action.

Thoroughly hardened concrete of good quality may be considered as resisting the action of acids and mineral oils as well as other building materials. Oils containing fatty acids may produce injurious effects by combining with the lime in the concrete, resulting in a disintegration of the latter.

Waterproofing Concrete. — Concrete may be made reasonably impervious to water under moderate pressures by using a rich mixture and by careful pro-

portioning and mixing. In the case of building foundations and other structures where leakage is not permissible it is usually advisable to protect the concrete by a separate coating applied either on the outside or inside of the wall or floor. The usual method of waterproofing the exterior is to construct a so-called membranous coating consisting of alternate layers of pitch and tarred felt. The inner surface of concrete basement walls and floors of many of the important buildings in New York City and other large American cities have been waterproofed by the use of a patented compound called "Hydrolithic Cement." Many so-called waterproofing powders, pastes, etc., are manufactured which are claimed to make concrete entirely water-tight if incorporated with it during mixing, but their value is problematical.

COMPRESSIVE STRENGTH AND WORKING STRESSES.—In the Joint Committee Report (*Proc. Am. Soc. C. E.*) the following table of compressive strength of thoroughly set concrete is given:

COMPRESSIVE STRENGTHS OF DIFFERENT MIXTURES OF CONCRETE

Set 28 days under favorable conditions

In Pounds per Square Inch

Aggregate	1:1:2	1:1½:3	1:2:4	1:2½:5	1:3:6
Granite, trap rock....................	3300	2800	2200	1800	1400
Gravel, hard limestone and hard sandstone........................	3000	2500	2000	1600	1300
Soft limestone and sandstone.........	2200	1800	1500	1200	1000
Cinders.............................	800	700	600	500	400

The following recommendations are also made:

When compression is applied to a surface of concrete of at least twice the loaded area, a stress of 32.5 per cent of the compressive strength may be allowed for static loads. This value may also be used for extreme fiber stress in a reinforced concrete beam.

For concentric compression on a plain concrete column or pier, the length of which does not exceed 12 diameters, 22.5 per cent of the compressive strength may be allowed for static loads.

For reinforced structures see the full report of the Committee in the *Proc. A.S.C.E.*, Feb., 1913.

Modulus of Elasticity.—The value of the modulus of elasticity of concrete has a wide range, depending on the materials used, the age, the range of stresses between which it is considered, as well as other conditions. It is recommended that in computations for the position of the neutral axis and for the resisting moment of reinforced concrete beams and for the compression of concrete in columns it be assumed as:

(*a*) One-fifteenth of that of steel, when the strength of the concrete is taken as 2200 lb. per sq. in. or less.

(*b*) One-twelfth of that of steel, when the strength of the concrete is taken as greater than 2200 lb. per sq. in., or less than 2900 lb. per sq. in., and

(*c*) One-tenth of that of steel, when the strength of the concrete is taken as

COST OF CONCRETE. — The following table* gives approximate costs of concrete in place. The values include superintendence, overhead charges and general expense but not office expense nor profit.

Item	Cost per cubic yard	
	Range	Average
Mass concrete as in dams, piers, foundations, etc.:		
Labor only	\$0.75 to \$2.50	\$1.25
Material and labor	3.00 to 9.00	5.50
Concrete in tunnels and conduits:		
Labor only	1.00 to 3.00	2.00
Material and labor	4.50 to 8.00	6.25
Concrete reservoirs and standpipes:		
Labor only	0.75 to 3.00	1.50
Material and labor	3.50 to 13.00	7.00
Concrete buildings:		
Labor only	0.75 to 4.00	1.50
Material and labor	4.50 to 9.00	6.50
Concrete bridges:		
Labor only	0.50 to 2.50	1.50
Material and labor	4.00 to 8.00	6.00
Concrete sewers:		
Labor only	0.75 to 1.75	1.50
Material and labor	3.50 to 8.00	6.00
Granolithic sidewalks:		
Labor only	1.00 to 3.00	1.75
Material and labor	6.25 to 9.00	7.00
Granolithic sidewalks:		
Labor only	2¢ to 4¢ per sq. ft.	2¾¢ per sq. ft.
Material and labor	5¢ to 14¢ per sq. ft.	10½¢ per sq. ft.

CONCRETE, REINFORCED. — (*See also Cement; Concrete; Structures, Simple.*) Reinforced concrete beams, girders and slabs are made of Portland cement concrete with the addition of steel bars or steel mesh to resist tensile stresses. They are usually fixed at the ends by being built into columns, walls, or other girders and are continuous over intermediate supports; they are, therefore, subject to negative bending moments at the ends and at intermediate supports and positive bending moments between supports. It is common to use bottom reinforcement throughout the length and top reinforcement across

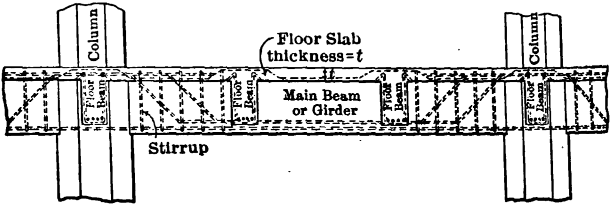

Fig. 1.

the supports. Vertical or inclined reinforcement is also usually necessary to carry the diagonal tensile stresses occurring in the web. Fig. 1 shows the general character of a reinforced concrete beam and shows methods of making connections to column and floor beams.

Character of Reinforcement. — The steel reinforcement may consist of round or square bars of which the diameter or side seldom exceeds 1½ inches. The square rods are sometimes twisted when cold, this type of bar being known as the Ransome bar. There are also various forms of corrugated or otherwise deformed bars on the market, some of which are shown in Fig. 2. Steel mesh is seldom used for ordinary beams, but is frequently employed in floor slabs. The steel reinforcement should preferably be of the same quality as that used for ordinary steel structures, although the use of a slightly less ductile material may be warranted in some cases where the steel is unlikely to be subjected to injurious shocks.

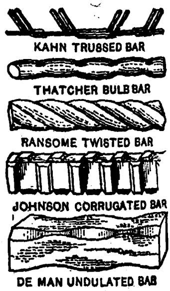

Fig. 2.

Proportions of Concrete; Forms. — The proportions of concrete for beams and other reinforced concrete structures subjected to flexure is commonly 1:2:4 (*see Concrete*). The forms or molds in which reinforced concrete beams are constructed are usually of wood bolted together, although steel forms are sometimes employed. In general, the size of the beam should be such that the forms can be manufactured from standard size boards. Forms should be watertight, and should be left in place until concrete has set sufficiently to carry the load to which it may be subjected at time of removal of forms.

Fireproofing. — In order to make reinforced concrete beams and columns fireproof the steel reinforcement must be protected by a reasonable amount of concrete. A common provision is that the metal in girder and columns be protected by a minimum of 2 inches of concrete; that the metal in beams be protected by a minimum of 1½ inches of concrete; and that the metal in floor slabs be protected by a minimum of 1 inch of concrete. It is also advisable that all

Spacing of Reinforcement. — Lateral spacing should not be less than three diameters center to center, with a clear spacing of not less than one inch. The distance from the side of the beam to the center of the nearest bar should be not less than two diameters. More than two layers should not be used unless securely tied together by metal connections particularly at or near points where bars are bent.

Electrolysis and Corrosion in Reinforced Concrete. — The best experimental data available indicate that no danger from electrolysis need be anticipated to the steel reinforcement in carefully mixed and proportioned Portland cement concrete free from salt or calcium chloride. Portland cement concrete may be considered to thoroughly protect embedded steel from corrosion provided the concrete is properly proportioned and mixed. If the concrete is porous, corrosion may be expected. See also article on *Electrolysis of Grounded Structures.*

Reinforced Concrete Beams. — The table on the following page gives the safe uniformly distributed loads per lineal foot for a series of reinforced concrete beams one (1) inch in width. The constants upon which the table is based are as follows: 1:2:4 concrete with ultimate compressive strength of 2000 pounds at 28 days. Allowable stress in concrete = 650 and in steel = 16,000 lb. per sq. in. Modulus of elasticity of steel 15 times that of concrete. Area of steel = 0.77 per cent area of beam above center of reinforcement.

FORMULAS FOR REINFORCED CONCRETE STRUCTURES. — Detail formulas for design cannot be given here; see references in *Bibliography.*

Reinforced Concrete Slabs. — These resemble beams, are much used for floors of buildings, and usually form an integral part of the floor beams and girders as indicated in Fig. 1. They may be computed in the same manner as reinforced concrete beams (*see above*) provided the shears and moments due to the outer forces are known. The distribution of the load may be determined by the application of the following formula recommended by the Joint Committee (*see Concrete*).

$$r = \frac{l^4}{l^4 + b^4},$$

in which r = proportion of load carried by the transverse reinforcement, l = length, and b = breadth of slab. For various ratios of l/b the values of r are as given in following table.

$\frac{l}{b}$	r
1	0.50
1.1	0.59
1.2	0.67
1.3	0.75
1.4	0.80
1.5	0.83

Using values above specified, each set of reinforcement is to be calculated in the same manner as slabs having supports on two sides only, but the total amount of reinforcement thus determined may be reduced 25 per cent, by gradually increasing the rod spacing from the third point to the edge of the slab.

If length of the slab exceeds one and five-tenths its width the entire load should be assumed as carried by transverse reinforcement.

Columns of Reinforced Concrete. — For such columns it is customary to limit to 15 the ratio of unsupported length to least width, and to consider the effective area as that within the protective coating (*see section on Fireproofing, above*), or for hooped columns or columns reinforced with structural shapes to the area within the hooping or structural shapes. The reinforcement may con-

sist either of longitudinal bars or of longitudinal bars connected by bands, hoops, or spirals, or of rigid structural forms. The following formulas may be used in design. Let A_c = cross-section of concrete, A_s = cross-section of steel, $A = A_c + A_s$ = total cross-section, n = ratio between modulus of elasticity of steel and concrete, usually 15, P = total safe load, f_c = allowable unit stress in concrete, f_s = allowable unit stress in steel, $p = A_s/A$. Then

$$P = f_c(A_c + nA_s) = f_cA[1 + (n - 1)p],$$

$$f_c = \frac{P}{A[1 + (n - 1)p]},$$

$$f_s = nf_c.$$

ALLOWABLE LOAD (POUNDS) ON REINFORCED CONCRETE BEAMS

Allowable uniformly distributed load in pounds per lineal foot, in excess of weight of beam, for end-supported rectangular reinforced concrete beams. *Tabular values to be multiplied by width of beam in inches to get safe applied load (dead + live + impact).*

[C. M. SPOFFORD.]

CONDENSERS, ELECTRIC. — (*See also Capacity and Charging Current.*) Any two conductors separated from each other by a dielectric form an electric condenser. The capacty C of such a condenser is the quotient of the numerical value of charge Q on either conductor by the difference of potential V between the two conductors *when equal and opposite charges are given the two conductors*, i.e., $C = Q/V$. The usual way of giving the conductors equal and opposite charges is to connect them respectively to the two terminals of a battery or other source of electromotive force. Unless the conductors are close to each other relative to the linear dimensions of their surfaces the capacity is small. Large capacities are usually obtained by using flat plates separated from each other by a thin sheet of dielectric. Unless the two conductors are close to each other relative to their distances from other conductors their capacity is influenced by the presence of the other conductors.

Formulas for Capacity. — See the article on *Capacity and Charging Current.*

Condensers in Series and in Multiple. — See *Electricity and Magnetism, Principles of.*

Energy Stored in a Condenser. — See *Electricity and Magnetism, Principles of.*

Electric Absorption and Dielectric Hysteresis in Condensers. — When an ordinary condenser is charged by connecting it to the terminals of a source of constant e.m.f. the amount of charge which it takes depends upon the time during which the e.m.f. is applied, i.e., there is an apparent absorption of charge by the dielectric. Time is also required for the dielectric to give up this charge when the plates are short-circuited. Absorption is particularly pronounced in such heterogeneous substances as glass, paper, ordinary mica, etc. On account of this absorption both the capacity and apparent resistance of a condenser in general depend upon the time of application of the e.m.f., i.e., upon the time of electrification.

Dielectrics, unless of perfectly uniform structure, when submitted to an alternating electrostatic field also manifest a property similar to magnetic hysteresis, that is, a certain amount of energy is dissipated in the dielectric as heat, over and above that corresponding to its "ohmic" or direct-current resistance. This loss is approximately proportional to the frequency of alternation of the electrostatic field, and consequently a condenser used in a high-frequency circuit does not have zero power factor, which would be the case were there no loss (*see Alternating Currents*).

TYPES OF CONDENSERS AND THEIR APPLICATION. — Condensers may be classified according to the nature of the dielectric used as: (1) air condensers; (2) mica condensers; (3) glass condensers; (4) paper condensers; and (5) electrolytic condensers.

Air Condensers. — Due to the low specific inductive capacity and relatively low dielectric strength of air, air condensers have very low capacity and are therefore seldom used except for standards of small capacity. For the latter purpose they are well suited, since their capacity is not appreciably affected by temperature, time of electrification, or frequency.

Mica Condensers. — On account of the high cost of suitable mica, condensers of this form are but little used except as standards. Mica suitable for such standards is not obtainable, except at prohibitive prices, in sheets larger than 3 inches by 4 inches. A good working thickness is from 0.0015 to 0.002 inch. A single sheet of high-grade mica 3 inches by 4 inches by 0.002 inch will give a capacity of about 0.004 microfarad and will withstand 1000 volts. In order that the insulation shall be high (product of megohms by microfarads not less

than 1000) and the absorption low, only sheets of the finest clear "ruby" mica should be used. The metal "plates" of mica condensers are usually of metal foil, preferably pure tin.

Fig. 1 shows the plan view and connection of a subdivided mica condenser. Since this arrangement permits of series, parallel, or series-parallel connection of the condensers a very large number of values of capacity may be obtained.

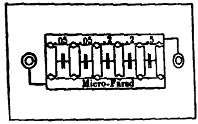

Fig. 1. Subdivided Standard Condenser

The power factor of well-made standard mica condensers ranges from about 0.1 per cent to about 1.75 per cent; see Grover, F. W., *Bulletin of the Bureau of Standards*, Vol. 3, No. 3.

Glass Condensers. — On account of its high dielectric strength and specific inductive capacity glass is particularly well suited for high-tension condensers, such as required for wireless telegraphy and the like. The Leyden jar is a common form of glass condenser. Moscicki's modification of the Leyden jar, shown in Fig. 2, consists of specially formed glass tubes closed at one end and coated inside with silver deposited chemically, the outer coating being sometimes applied in the same way and sometimes dispensed with altogether, the outer electrode in the latter case consisting of a mixture of glycerine and water in which the tubes are immersed.

Fig. 2. Moscicki Condenser

Mordey (*Jour. Inst. Elec. Eng., 1909, Vol. 43, p. 621*) reports a test on a Moscicki condenser consisting of 8 tubes having a total capacity of 0.03 microfarad, designed for 10,000-volt a-c. working. Each tube is 2 inches in diameter and 2 feet 9 inches long, or with connections 3 feet 2 inches long. The power factor of this condenser was approximately constant and equal to 1.0 per cent for frequencies from 40 to 60 cycles per second and for voltages from 5000 to 10,000 volts.

Condensers of this type are used to a considerable extent in Europe as a protective device on high-tension overhead transmission lines, as well as for wireless telegraphy. It has also been suggested by Mordey that they could be used economically for improving the power factor of highly-inductive loads, such as induction motors.

Paper Condensers. — These are made either (1) by building up a stack of alternate sheets of tinfoil (0.0003 inch thick) and tissue paper, two sheets to the layer, each sheet about 0.001 inch thick, or (2) by rolling up alternate strips of foil or "foiled" paper and tissue paper, the roll after being dried and impregnated with paraffin or other wax being pressed into a cubical shape, and suitably mounted in airtight metal boxes. The "foiled" paper is made by depositing very fine flakes of tin on suitable tissue paper which is then run through a press which forces the flakes into contact with each other, resulting in a paper resembling the so-called silver paper used for wrapping tea but having a fairly high conductivity. According to G. F. Mansbridge (*see reference below*) this paper possesses two decided advantages over the ordinary metal foil, (1) it is much lighter, and (2) when punctured it is self-healing, the spark vaporizing the tin in the immediate vicinity of the puncture without destroying the paper itself. For a complete description of the method of making the paper and the condensers see Mansbridge, G. F., *Jour. Inst. Elec. Eng.*, 1908, Vol. 41, p. 535.

Paper condensers are used almost exclusively for telephone and telegraph work. They are usually built to withstand about 400 volts. The following

weights and dimensions are taken from the British Post Office specifications for metal-cased telephone condensers. One-microfarad paper condensers designed for a working pressure of 1000 volts, and having the dimensions 8¾ by 6¼ by ½ inches and weighing 8 ounces each are made by the Western Electric Co.

DIMENSIONS AND WEIGHT OF PAPER CONDENSERS

British Post Office Specifications

Capacity, microfarads	Length, inches	Width, inches	Thickness, inches	Weight, ounces
0.5	4¾	2⅝	5/16	4
1.0	4¾	4¾	5/16	8
2.0	4¾	4¾	9/16	12
4.0	4¾	4¾	1⅛	20
10.0	4¾	4¾	2 11/16	46

The power factor of well-made paper condensers ranges from about 0.2 to 2 per cent, but unless care is taken in their manufacture the power factor may be considerably larger; values as high as 30 per cent have been obtained.

Electrolytic Condensers. — Electrolytic cells of the three following types have been used to a limited extent in Germany as condensers for telephone work: (1) acid cells, consisting of two small electrodes of platinum dipping into an acid solution, (2) sodium cells, in which the electrolyte is a solution of common salt, and (3) aluminum cells, in which the electrodes consist of aluminum and the electrolyte is some kind of basic solution. The capacity action of these cells arises from the formation of an extremely thin insulating layer at the anode of the cell which apparently has an enormously high specific inductive capacity. The anode and electrolyte therefore form two plates of a condenser having this thin layer of dielectric between them, forming a condenser of exceptionally large capacity per unit volume. The power factor of this condenser, however, is very high, due to the leakage current from anode to electrolyte, and consequently these cells are little used strictly as condensers, either in telephone or in power work. However, the aluminum cell is very extensively used as a lightning arrester, on power circuits, its capacity action combined with the self-heating property of the film making it an excellent device for this purpose (*see Lightning Protectors*).

TESTING OF CONDENSERS. — The three important properties of a condenser are its capacity, its insulation resistance and its power factor. The insulation resistance is determined by the use of direct current (*see Resistance and Conductance*); the power factor is measured by employing a source of alternating e.m.f., and may be looked upon as a measure of the effective a-c. resistance. Since this effective resistance is usually many times greater than the d-c. resistance, and since it varies directly as the frequency, the power factor of a condenser is practically constant for a considerable range in frequency.

A great many arrangements of circuits have been devised for measuring the capacity of condensers, cables, etc. Only one or two of the simple methods used in engineering practice can be described here. For a description and comparison of the various methods which have been used see Grover, F. W., *Bulletin of the Bureau of Standards*, Vol. 3, No. 3.

D-C. Versus A-C. Capacity Tests. — Due to the effect of electric absorption above described, the charge taken by a condenser depends upon the time

of electrification; the discharge also depends on the time. Consequently, when the capacity is measured by any direct-current scheme a standard time of electrification and a standard method of determining the discharge must be chosen. The British Post Office call for the capacity to be measured by taking the instantaneous discharge (by ballistic galvanometer) after the condenser has been charged for a period of 10 seconds. As a rule the capacity measured by a-c. methods is less than that measured by d-c. methods, since the charge does not have time to soak in; for the same reason the a-c. capacity also decreases slightly with increase of frequency. Hence a-c. tests should be made at a standard frequency, preferably that of the circuit on which the condenser or cable is to be used. It is also desirable, when possible, to make the capacity test at the same voltage, both in value and wave form, as is to be used on the condenser.

Voltmeter-ammeter Test of Capacity. — Connect the condenser in series with an a-c. ammeter and impress on this circuit the selected a-c. voltage. Measure the voltage drop across the condenser by means of a high-resistance a-c. voltmeter. Let the current read by the ammeter (voltmeter circuit open) be I, the voltmeter reading V, the frequency f, then the capacity is

$$C = \frac{I}{2\pi f V},$$

provided the voltage is a pure sine wave and the power factor of the condenser is negligible. As neither of these conditions are usually fulfilled, such a test as a rule gives only a rough approximation to the true capacity.

Ballistic Galvanometer Method. — Fig. 3 shows the arrangement of circuits for testing the capacity of a cable. B is a battery giving the desired constant e.m.f., K a highly insulated key, G a ballistic galvanometer properly shunted (*see Galvanometers and Shunts*). The sheath of the cable is usually necessarily earthed. It is best to charge the core of the cable positively as shown. If a condenser is to be tested instead of a cable, the plate corresponding to the sheath may or may not be earthed, as desired. Care should be taken that there is no leakage of current directly from the battery into the galvanometer or into the cable.

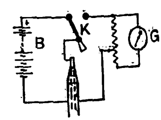

Fig. 3.

The procedure is as follows: Throw the key to the left for the desired length of time, note the position of the galvanometer needle (or spot of light), then throw the key to the right and note the first swing or maximum deflection of the spot of light. Call this D_x. Next, keeping the same battery, substitute for the cable a standard condenser of known capacity C and make a similar observation. Let the deflection in this case be D. Then the unknown capacity is

$$C_x = \frac{D_x}{D} C,$$

provided the damping of the galvanometer is the same in both cases.

While this method is satisfactory when applied to perfect condensers, it fails to a greater or less extent when applied to cables, especially if they are very long, or to any condenser having high absorption. With such condensers the discharge consists of two portions: a sudden rush when the key is first closed, followed by a current gradually diminishing toward zero, due to the release of the "absorbed" charge. Both portions of the discharge are active in producing the deflection, hence the apparent capacity depends to a certain extent on the period of the galvanometer employed, as well as upon the time of electrifi-

Wheatstone Bridge Method. — The following method gives a means of measuring both the capacity and power factor of a condenser, provided there is available a standard condenser whose capacity and power factor is known. The bridge is arranged as shown in Fig. 4. C is the standard condenser and C_x the condenser to be tested. All resistances must be non-inductive and adjustable. A is a source of alternating e.m.f. of pure sine-wave form and of frequency f. T is the detector; it may be either a telephone or, if the frequency be kept perfectly constant, a vibration galvanometer. For ordinary tests the telephone is the more convenient instrument; for good work with it the frequency should be high.

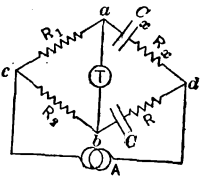

Fig. 4.

The balancing is effected as follows: with R_x and R both zero, adjust R_1 or R_2 until a minimum of sound is obtained; then adjust either R_x or R as the case may require, until the minimum is the best possible; then readjust R_1 or R_2, and so on, thus obtaining the perfect balance by successive adjustments.

$$C_x = \frac{R_2}{R_1} C,$$

$$\tan \phi_x = \tan \phi + 2\pi f (RC - R_x C_x),$$

where f is the frequency, ϕ_x is the angle whose *sine* is equal to the power factor of the condenser under test and ϕ is the angle whose *sine* is equal to the power factor of the standard condenser. The effective alternating-current conductance of the condenser under test is then

$$G_s = 2\pi f C_x \tan \phi_x,$$

which as a rule is many times the reciprocal of its insulation resistance as measured by direct-current methods (*see Resistance and Conductance*).

The value of the power factor for the standard is best determined at the Bureau of Standards in Washington; it is done by indirect reference to an air condenser.

Sources of Error. — The sources of error when the most refined measurements are to be made are the inductance or capacity of the various resistances, error in the ratio of R_1 and R_2, and electrostatic induction between the bridge and its surroundings. These sources of error are fully discussed by Grover above referred to.

COST OF CONDENSERS. — A good standard mica condenser of 1/3 microfarad, guaranteed to stand 300 volts maximum across its terminals costs about \$25. An adjustable mica condenser, such as shown in Fig. 1, having a maximum capacity of 1 microfarad and suitable for voltages up to 300 volts costs about \$60. Paper condensers, such as used on telephone circuits, cost about 70 cents per microfarad. A standard 1000 volt, 1 microfarad paper condenser can be had for about \$3.75.

[H. PENDER AND H. R. RANKEN.]

CONDENSERS, STEAM.— (*See also Cooling Systems for Power Stations; Power Stations; Pumps; Steam Engines; Turbines, Steam.*) The primary object of a condenser is to reduce the back pressure in the exhaust of a steam-engine or steam turbine, although in cases where the supply of suitable feed water is limited the recovery of the condensed steam is of equal importance. Theoretically the gain in the output of a given engine for the same steam input is proportional to the reduction in back pressure, but practically the gain is usually much less than this, depending upon the type of engine and conditions of operation.

CLASSIFICATION OF CONDENSERS. — Condensers are of two general types, jet condensers and surface condensers.

Jet Condensers. — In a jet condenser cooling water and the exhaust steam mingle together in a closed chamber, the water condensing the steam by direct contact. The cooling or injection water on entering the condenser is broken up into a fine spray or is spread out into a thin sheet. Jet condensers may be classified as follows:

Standard or Ordinary Jet Condensers, in which the cooling water, condensed steam and air are exhausted by a pump.

Barometric Condensers (Siphon Condensers), in which the cooling water and condensed steam are exhausted by a barometric column, the air being exhausted with the water and condensed steam or by means of pump. In certain types of barometric condensers the condensing water is forced into the condenser by atmospheric pressure (if the lift of the condensing water is not over 15 feet), and the condenser is then called a "siphon" condenser.

Ejector Condensers, in which the condensed steam and air are exhausted directly to the atmosphere by the momentum acquired by the cooling water and condensed steam as they pass through the condenser.

Rotary Condenser. — The best known form of this type of condenser is the Leblanc Condenser (made by the Westinghouse Machine Co.), which accomplishes the separate removal of water and air by means of a pair of relatively small turbine-type rotors on a common shaft in a single casing, which is integral with or attached directly to the lower portion of the condensing chamber. The condensing chamber itself is but little more than an enlargement of the exhaust pipe. The injection water is projected downwards through a spray nozzle, and the combined injection water and condensed steam flow downward to a centrifugal discharge pump under a head of 2 or 3 feet, which insures the filling of the pump. The space above the water level in the condensing chamber is occupied by water vapor plus the air which entered with the injection water and with the exhaust steam. This space communicates with the air-pump through a relatively small pipe.

The air-pump differs from pumps of the ejector type in that the vanes in traversing the discharge nozzle at high speed constitute a series of pistons, each one of which forces ahead of it a small pocket of air, the high velocity of which effectually prevents its return to the condenser. A small quantity of water is supplied to the suction side of the air-pump to assist in the performance of its functions. The power required for the pumps is said to approximate 2 to 3 per cent of the power generated by the main engine.

Surface Condensers. — Ordinary surface condensers consist of nests of small brass or copper tubes usually ¾ inch or 1 inch in diameter through which cooling water is forced and which are surrounded by an air-tight shell to which the exhaust steam is admitted. There may be one, two or more sets of tubes through which the steam passes in succession, the condenser being referred to

as a "single-flow," "double-flow" or "multi-flow" respectively. Steam is admitted at the top of the shell and the condensed steam drawn off at the bottom. Water enters the lower tubes and is discharged at the top, securing thus the advantages of the counter-flow principle. The rate of heat transmission depends largely upon the state of the tubes. Transmission is much retarded by a water film coating the exterior of the tubes and by interior coatings of scale, dirt or corrosion. In the so-called "dry-tube" type baffles are arranged to catch the drip from each set of pipes, drain it off at the side and so prevent it from falling on the pipes below.

Evaporative and Air-cooled Surface Condensers are sometimes employed when condensing water is scarce. Brief descriptions and references will be found in Gebhardt's *Steam Power Plant Engineering*.

List of Well-known Condensers. — The following are some of the well-known condensers.

Jet Condensers:
- Ordinary
  - Worthington.
  - Blake.
  - Deane.
- Barometric.
  - Weiss.
  - Alberger.
  - Rotary.
  - Leblanc.

Surface Condensers:
- Baragwanath (single-flow).
- Wheeler (double-flow).
- Wainwright (multi-flow).

CLASSIFICATION OF CONDENSER PUMPS. — (*See also Pumps and Pumping Engines.*) The following names are usually applied to the pumps used in connection with a condenser.

Injection or Circulating Pump, the pump used for injecting the cooling water into a condenser.

Wet-air Pump, the pump used for exhausting the air, condensed steam and hot water from a condenser when these are all exhausted together.

Dry-air Pump, the pump used for exhausting the air and water vapor only. A dry-air pump must be used when high vacua are required.

Hot-well Pump. — This name is applied to the wet-air pump when this pump exhausts to a hot-well. The hot-well is a well provided to hold the condensed steam, which is approximately at the same temperature as that of the exhaust steam in the condenser. If this hot water is to be used over again for boiler feed it is pumped from the hot-well to the boiler by the boiler feed pump (*see Boilers, Steam*).

CHOICE OF TYPE OF CONDENSER. — The chief advantage of the surface condenser over the jet condenser is that the condensed steam does not mingle with the cooling water and therefore the condensed steam may be used over again for boiler feed water, provided any oil which may be carried by the exhaust steam from the cylinders is eliminated before the steam reaches the condenser (*see Separators, Steam*). When there is plenty of cooling water readily handled a higher vacuum is usually obtained by means of a surface condenser than by means of a jet condenser. To offset these advantages, however, the surface condenser is much more expensive than a jet condenser, and requires as a rule a greater amount of cooling water.

Consequently the use of a surface condenser is in general justified only when the cost of obtaining suitable feed water is relatively high (*see also Feed-water Heaters and Purifiers*), and cooling water, unsuitable for feed water however,

relatively cheap (*see also Cooling Towers, Ponds, etc*). Before finally selecting either type of condenser an estimate of the total annual cost, including interest, depreciation, maintenance and all operating charges should be made for each case.

According to Prof. Wickenden the following vacua, based on a 30-inch barometer, have been found most economical in general practice.

Piston engines	26 to 26.5 inches
Turbines at 20 per cent load-factor or less	27 to 27.5 inches
Reaction turbines at high load-factors	28 to 29.5 inches
Impulse turbines at high load-factors	28.5 to 29 inches

In summer months warm cooling water often renders these vacua impracticable. When cooling towers are required to conserve the water supply the economic limits of vacuum are lower, due to the extra investment and the relatively warm state of the water. Jet condensers are cheaper to install and operate for vacua up to 27 inches. They require less water and give somewhat higher hot-well temperatures if closely regulated. For higher vacua the load on the dry-air pump becomes excessive, due to the air entrained with the cooling water. Surface condensers are then preferable and for extreme vacua they are indispensable.

DEGREE OF VACUUM AND BACK PRESSURE. — Let

V = degree of vacuum, i.e., the reading of vacuum gauge, in inches of mercury column,

B = reading of barometer.

Then the back pressure in pounds is

$$p = 0.491\ (B - V).$$

The degree of vacuum is usually referred to a barometric pressure of 30 inches. Calling V_0 the vacuum in inches of mercury corresponding to a barometric pressure of 30 inches, and B and V the observed barometric pressure and gauge reading respectively, then

$$V_0 = V + (30 - B).$$

(If V_0 is the vacuum in inches referred to 760 millimeters or 29.91 inches of mercury, substitute for 30 the number 29.91.)

Vacua from 20 to 29 inches are used in practice, corresponding to back pressures of from 4.5 to 0.5 pounds. The higher the vacuum the more cooling water required and the greater the cost of the air and circulating pumps.

CONDENSING WATER REQUIRED. — Let

T = temperature, in ° F., of dry saturated steam at the pressure corresponding to the desired degree of vacuum,

T_i = temperature, in ° F., of the injection water,

T_s = temperature, in ° F., of the condensed steam at bottom of condenser,

T_w = temperature, in ° F., of the discharge water (for a jet condenser $T_w = T_s$),

H = total heat (above 32° F.) of the exhaust steam, in B.t.u. per pound.

Then the weight of condensing water required per pound of steam is

$$W = \frac{H - T_s + 32}{T_w - T_i}.$$

In applying this formula the values of T_s and T_w must be determined and an allowance must be made for the regulation of the supply of condensing water.

Values of T_s and T_w. — Air is always present in exhaust steam and in the case of jet condensers a certain amount of air also enters the condenser with

the cooling water. The effect of the air is to reduce the temperature of the steam (T_s) below that corresponding to saturated dry steam (T) at the same pressure. The amount of air present depends upon the type of condenser and also upon the amount of air in the cooling water in the case of a jet condenser. The following relations between T_s, T_w and T are found to hold in practice.

	Jet condensers		Surface condensers	
	Parallel-current	Counter-current	Single and double flow	Multi-flow*
	Deg. F.	Deg. F.	Deg. F.	Deg. F.
T_s less than T by....................	10 to 15	5 to 10	5 to 10	0 to 5
T_w less than T by....................	10 to 15	5 to 10	10 to 20	0 to 10

* Cases have been reported where T_s and T_w are both *higher* than T by a few degrees. (*Proc. Inst. Nav. Arch., March*, 1906.) [Probably due to errors of gauges.]

Allowance for Regulation of Injection Water. — It is usual to take for H in the above formula the value corresponding to dry saturated steam at the given pressure in the condenser (*see tables in article on Steam*), and then to increase the value of W so obtained by from 5 to 15 per cent to allow for imperfect regulation of the injection water and for the more or less unknown state of the steam as it enters the condenser.

Example. — A vacuum of 25.85 inches, referred to 29.92-inch barometer, is to be maintained in a surface condenser, with injection water at 60° F. The value of T from the steam tables is 126° F. and H = 1115 B.t.u. Take T_s = 120°, T_w = 115°, T_i = 70°; then

$$W = \frac{H - T_s + 32}{T_w - T_i} = \frac{1115 - 120 + 32}{115 - 70} = 22.8.$$

DIMENSIONS OF CONDENSERS. — There is so great a difference in the design of the various forms of jet condensers that it is impossible to give any average dimensions. See the catalogues of the makers; representative makes of the various types are listed above.

In the case of surface condensers the tube surface exposed to the steam varies inversely as the coefficient of heat transfer (i.e., the number of B.t.u. per hour per ° F. difference in temperature between the steam and water per square foot of cooling surface) and directly as the mean temperature difference between the water and the steam. Let

T_i = temperature, in ° F., of the injection water,
T_s = temperature, in ° F., of the exhaust steam at condenser pressure,
T_w = temperature, in ° F., of the discharge water,
Q = pounds of cooling water required per hour,
U = coefficient of heat transfer.

Then, according to Josse (*Power, Feb. 2, 1909*), the required cooling surface in square feet is

$$S = \frac{2.3\,Q}{U} \log_{10} \frac{T_s - T_i}{T_s - T_w}.$$

The value of U depends upon the metal used for the tubes, the condition of the external surface of the tubes and especially upon the condition of the internal surface of the tubes (scale and corrosion decreasing the value of U very markedly),

and upon the velocity of the water, being greater the higher this velocity. U may be taken as 250 for water velocities of from 25 to 50 feet per minute and 375 for velocities of from 50 to 75 feet per minute. There is, however, considerable difference of opinion regarding the proper formula for S and the proper value to assign to U.

In reciprocating engine plants an allowance of 2 square feet of tube surface per indicated horse-power is customary. In early steam-turbine installations an area of from 2 to 4 square feet per kilowatt was commonly employed, but subsequent improvements in condensers and the water rates of turbines have tended to reduce these areas. In the most modern plants of large capacity condenser surfaces range from 1.2 to 2.5 square feet per kilowatt.

From the relations implied in the above formulas it is seen that the surface may be reduced by forcing large quantities of water at high velocities to pass the tubes; or, with a given surface, the vacuum may be heightened by increasing the flow of cooling water. However, the gain may be more than offset by the cost of pumping this water.

SIZE OF CONDENSER PUMPS. — (*See also articles on Blowers and Compressors; Pumps and Pumping Engines.*) The size of the injection or circulating pump required can be calculated directly from the quantity of injection water to be handled and the head against which it is to be pumped, including of course the friction head. Separate injection pumps for jet condensers are not usually required, as the head does not as a rule exceed that corresponding to the difference between atmospheric and condenser pressure. In the case of surface condensers the intake and discharge tunnels are usually at about the same level, and consequently the head is largely friction head. The friction head of a condenser is not readily calculated, but may be obtained from the manufacturer.

Wet-air Pumps. — The predetermination of the size of wet-air pumps is difficult, owing to the uncertainty in estimating the quantity of water vapor and air which they must handle. In the case of jet condensers the total weight of water (including the vapor) and air is equal to the combined weight of the exhaust steam and cooling water, whereas for a surface condenser only the condensed steam and air in it is handled by the wet-air pump. Hence the wet-air pump for a surface condenser is usually much smaller than for a jet condenser.

Formulas, partly analytical and partly empirical, for calculating the piston displacement of wet-air pumps will be found in Gebhardt's *Steam Power Plant Engineering*. For average practice the volume capacity or piston displacement is equal to the volume of *cooling water* multiplied by the following factors.

For jet condensers, single-acting pump.......................... 3
For jet condensers, double-acting pump.......................... 3.5

Piston speeds are usually about 50 feet per minute at full load.

For surface condensers the volume capacity is equal to the volume of the *condensed steam* multiplied by the following factors.

For reciprocating engines.......................................10
For steam turbines..20

These figures are based on a study of some 200 installations (Gebhardt, 1910 ed.).

Dry-air Pump. — The required volume capacity is found in practice to be equal to the volume of the *condensed steam* multiplied by the following factors:

For vacua under 27 inches............................ 20 to 30
For vacua 28 inches or over.......................... 50

In both cases the barometer is assumed as 30 inches. These figures are given by Gebhardt and are based on an investigation of some 50 installations.

POWER REQUIRED FOR CONDENSER PUMPS. — The power required for the circulating pump is calculated in the ordinary way from the weight of the water delivered and the head, including the friction head (*see article on Pumps and Pumping Engines*).

The power required for the wet-air and dry-air pumps can be accurately determined only when the proportion of air in the exhaust steam and also in the cooling water, in the case of a surface condenser, is known. Surface water under atmospheric pressure contains from 2 to 12 per cent, by volume, of air. To allow for leakage, a liberal factor of 20 per cent may be taken.

Power Required to Exhaust the Air. — Let

p_a = atmospheric pressure, pounds per square inch,
p_c = pressure in condenser, pounds per square inch,
T_i = initial temperature of injection water, in ° F.,
T_f = initial temperature of feed water, in ° F.,
T_c = temperature in condenser in ° F. (approximately the temperature of the exhaust steam),
W_w = weight of cooling water in pounds per *minute*,
W_s = weight of condensed steam in pounds per *minute*.

Then for a jet condenser the volume of air in cubic feet per minute at condenser pressure to be handled by the pump is

$$V_1 = \frac{(W_w + W_s)\, p_a\, (T_c + 460)}{310\, p_c\, (T_i + 460)},$$

and for a surface condenser

$$V_1 = \frac{W_s p_a\, (T_c + 460)}{310\, p_c\, (T_f + 460)},$$

assuming in both cases that there is 20 per cent air by volume in the water at atmospheric pressure. This percentage is probably high when the feed water is taken from a hot-well, since the heating of the water drives out the air. Also, the temperature T_c for a counter-current jet condenser and separate air pump is more nearly the temperature of the injection water than that of the steam.

The horse-power required to exhaust the air is then

$$P_a = \frac{p_c V_1}{66.2\,\epsilon} \left\{ \left(\frac{p_a}{p_c} \right)^{0.29} - 1 \right\},$$

where ϵ is the mechanical efficiency of the pump, which may range from 30 to 60 per cent. (*See article on Blowers and Compressors.*)

Power Required to Exhaust the Condensed Steam and Water. — The power required to exhaust the water and condensed steam from a jet condenser may be calculated in the same manner as for an ordinary pump (*see article on Pumps and Pumping Engines*), using the proper value of the head under which the pump operates. This will depend upon the arrangement of the condenser, location of the pumps and hot-well, etc.

If a wet-air pump only is used, then the total horse-power of this pump will be $P_a + P_w$, where P_w is the horse-power required to remove the condensed steam and water. If a dry-air pump is used in connection with the wet-air pump (which then exhausts the water only) the horse-power of the dry-air pump is P_a, and the horse-power of the wet-air pump P_w.

Per Cent of Total Available Energy Used by Condenser Pumps. — When steam-driven pumps are employed and the exhaust from these pumps is not utilized the steam consumption of the pumps is properly taken as a measure of the energy required for their operation; this may range from 5 to 20 per cent

of the total steam generated by the plant. When the exhaust from the steam cylinders of the pumps is utilized for heating the feed water (see *Feed-water Heaters*), the *heat consumption* of the pumps is properly taken as a measure of the energy required for their operation; this may range from about 1 to 5 per cent of the total B.t.u. utilized by the main engines, for a large part of the heat in the steam used in the pumps is returned to the boiler via the feed water. When electrically-driven pumps are employed, the kilowatt-hour input to the motors driving the pumps is properly taken as a measure of the energy required for operating the pumps; this may range from about 2 to 8 per cent of the output of the main generators.

LOCATION AND ARRANGEMENT OF CONDENSERS. — Where there is only one engine installed the condenser is usually placed close to and just below the engine, so that all condensation may gravitate into it. In some large vertical steam turbine outfits the condenser (surface type) is at the base of the turbine and forms an integral part of the structure. When several engines or turbines are installed in a power house a separate condensing outfit may be used for each engine, or the so-called "central system" may be employed in which one condensing outfit serves several engines. This arrangement is particularly well adapted to plants in which the individual units are subjected to extreme variations in load, as in rolling mills.

Additional data on the location and arrangement of condensers will be found in the article on *Power Stations*.

COST OF CONDENSING EQUIPMENT. — The cost of condensing equipment depends upon the amount of steam to be condensed, the degree of vacuum to be maintained, the type of equipment and the method of driving the pumps. Gebhardt gives the following cost per kw. of generator output for the complete condensing equipments installed and ready for operation.

Siphon condensers without air pump	$2.00-$3.00
Jet condensers (ordinary)	3.00- 4.50
Barometric condensers with dry-air pump	4.00- 6.00
Surface condensers for 26-inch vacuum	3.50- 5.00
High-vacuum surface condensers	3.50-10.00
Leblanc jet condensers and pumps	2.00- 6.00

J. R. Bibbins (*Power, Jan.*, 1905) gives a curve showing the relative cost of high-vacuum surface condensers compared with 26-inch-vacuum surface condensers. The following figures are taken from this curve.

Degree of vacuum, inches	26	26.5	27	27.5	28	28.5
Relative cost, per cent	100	111	123	137	158	205

Maintenance of Condensers. — The cost of maintenance of a surface condenser is subject to wide variations, depending upon the corrosion and deterioration of the condenser tubes, the exact cause of which is not often understood. With clean, fresh water, free from acid, the tubes of a condenser last indefinitely, but where the cooling water contains sulphur, as in drainage from coal mines, or sea water contaminated by sewage, such as harbor water, the deterioration is exceedingly rapid.

The maintenance of a jet condenser is much less affected by impurities in the water.

BIBLIOGRAPHY. — Gebhardt, *Steam Power Plant Engineering*, N. Y., 1909, contains 62 pages on condensers and a very full bibliography of the subject.

[WM. KENT.]

CONDUITS AND CONDUIT LINES, UNDERGROUND. — (*See also Distribution Lines; Transmission Lines; Wires and Cables, Insulated; Wiring of Buildings.*) The following is a brief table of contents of this article:

Underground cables are now almost universally installed in conduits made either of glazed tile, wood or paper fiber. The pipes or conduits are laid so as to form a series of continuous ducts for a length of not over 400 feet, and are terminated in brick or concrete chambers, from which the cables are pulled into the ducts.

TERMINOLOGY. — While there is some confusion in the terminology of conduit lines, the best recent literature sanctions the following definitions.

Conduit, a pipe or tube designed or used for containing electric wires or cables.

Duct, a passage or opening, designed or used for accommodating electric wires or cables.

Conduit Line, a group of installed conduits. (The expression *subway* is largely used for conduit line, but will not be used herein, as it is desired to avoid such expressions as "the subway subway," meaning the conduit lines of an underground railway.)

Splicing Chamber, a chamber built to give access to the ducts of a conduit line; frequently called a manhole. Properly, a manhole is the opening giving access to the spliting chamber.

Manhole, an opening giving access to an underground splicing chamber, from the surface of the ground; frequently, but improperly, used to designate the entire splicing chamber.

Service Box, a part of a splicing chamber with facilities for connecting distributing conductors to the mains. Service boxes are usually made of cast iron and set on the roof of the splicing chamber like a manhole casting.

USE OF CONDUIT LINES. — Conduit lines are used for the distribution of electrical energy wherever the unsightliness, danger or instability of pole lines prohibits the use of the latter. It is therefore in large cities that they have found their principal application. They are used for the transmission and distribution cables of lighting systems, power plants and railways, and for telephone and telegraph lines.

Since the invention of the Pupin loading-coil, the use of conduit lines for telephones has received considerable impetus. Underground telephone lines now extend from Boston to Washington, a distance of nearly 500 miles, creosoted pump-log being used for the conduit the greater part of the way. The most notable installation of conduit for trunk-line railroad electrification is that of the New York Central which comprises over 1,600,000 duct feet, partly in tile conduit and partly in iron pipe.

Advisability of Double-conduit Line. — A conduit line of a large number of ducts should be avoided wherever possible. While a large line may be per-

missible for telephone work, it certainly is not desirable for light or power work. The entire output of a station or substation of considerable size should not be carried out through one conduit line, but should be divided between two or more lines kept well separated.

TYPES OF CONDUITS. — While tile conduit is used far more than any other kind, there are four other kinds in fairly extensive use; namely, fiber conduit, wrought-iron pipe, cement-lined iron and pump-log.

Tile Conduit. — Figs. 1 and 2 show the tile conduits used in the Electric Zone of the N. Y. C. & H. R. R.R. near New York. They represent what is

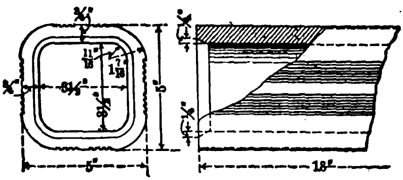

Fig. 1.

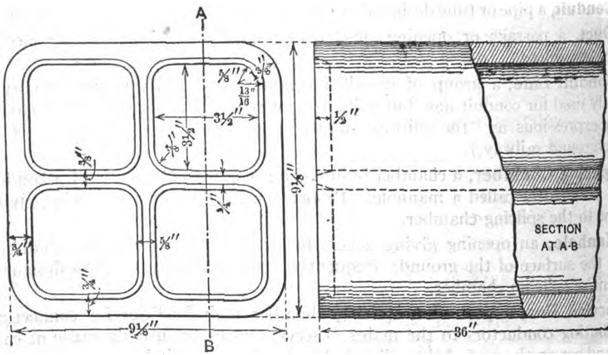

Fig. 2.

probably the best practice up to date. The single-duct conduit weighs 16½ pounds per length of 18 inches, and the four-duct conduit weighs 100 pounds per length of 3 feet.

Fiber Conduit consists of tubes, made by rolling paper saturated with asphalt or bituminous compound around a mandrel. Like iron pipe, which it resembles in appearance, lengths of fiber conduit are usually joined by screw and coupling although it is also made for socket, sleeve and drive joints. It is lighter and easier to handle than iron pipe with which it compares favorably in cost, but is more expensive than tile conduit. It is mechanically inferior to other types of conduit, and difficulty is often experienced in drawing heavy cable around bends without breaking the conduit. For some classes of work this disadvantage is entirely compensated for by superior gas and water tightness.

The dimensions of fiber conduits are given as follows by the Johns-Manville Company and substantially the same by the Fiber Conduit Company.

Socket joint				Sleeve joint			
Inside diameter, inches	Thickness of walls, inches	Approximate average weight per foot, pounds	Length of section, inches	Inside diameter, inches	Thickness of walls, inches	Approximate average weight per foot, pounds	Length of section, inches
1	1/4	0.45	30	1	1/4	0.45	30
1 1/2	1/4	0.75	60	1 1/2	1/4	0.75	60
2	1/4	0.90	60	2	1/4	0.90	60
2 1/2	1/4	1.05	60	2 1/2	1/4	1.05	60
3	1/4	1.30	60	3	1/4	1.30	60
3 1/2	1/4	1.60	60	3 1/2	7/16	2.50	60
4	1/4	1.85	60	4	1/2	3.20	60
Screw joint				**Drive joint**			
1 1/2	5/16	0.85	60	2	1/4	0.90	60
2	3/8	1.35	60	2 1/2	1/4	1.05	60
2 1/2	3/8	1.70	60	3	1/4	1.30	60
3	7/16	2.20	60	3 1/2	1/4	1.60	60
3 1/2	7/16	2.50	60	4	1/4	1.85	60
4	1/2	3.20	60				

Wrought-iron Pipe is used in city streets where the conduit line has to twist about sub-surface obstructions. It is more expensive than tile conduit and does not last as long on account of rusting. The usual sizes are 3-inch and 3 1/2-inch pipe, 20 feet long, provided with threaded ends and couplings. (For weights and dimensions see article on *Pipes*.)

Cement-lined Iron Pipe consists of thin sheet-iron cylinders, like stovepipe, with a lining of hydraulic cement. When the conduit is old the iron usually rusts away without detriment to the construction.

Pump-log Conduit is used only on telephone lines, as its inflammability renders it dangerous for power work. It consists of wooden blocks with the

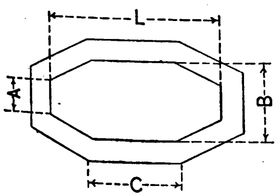

Fig. 3.

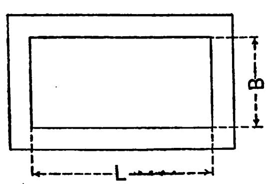

Fig. 4.

duct hole drilled out. A description of a typical pump-log installation is given below under Installation.

SPLICING CHAMBERS. — Splicing chambers, for straight runs, are usually built in the shapes shown in Figs. 3, 4, 5 and 6. That shown in Fig. 3 is usually regarded as ideal, as the excavation is a minimum, and the cables can

follow the walls very closely without being bent to a dangerously small radius, a frequent occurrence in chambers with square corners. The rectangular form shown in Fig. 4 is somewhat more common, but requires more excavation and more wall material than the first form, and is conducive to sharp bends in the

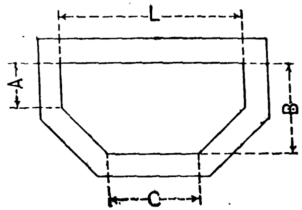

Fig. 5.

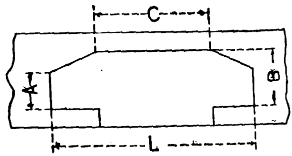

Fig. 6.

cable. The type shown in Fig. 5 is convenient where it is desired to have a wide chamber without occupying much space on one particular side of the duct line as, for example, where two duct lines run parallel and a short distance apart. In this case, economy may be obtained by the use of a common wall on the long side of the chamber.

Fig. 6 shows the side-wall type of chamber, which is entered from the side instead of the top. This form is used in the side walls of tunnels or in retaining walls, and usually takes the form of a long niche in the wall. When built in tunnel walls not far from the surface of the ground, it is desirable to have them open from the street above as well as from the side, in order to avoid the necessity of having the use of a tunnel track when work is to be done in the chambers.

Material of Splicing Chambers. — Monolithic concrete is the cheapest and best material to use where a large number of identical chambers have to be built, as the same form can be used over and over again. Where such uniformity cannot be attained, as in streets congested with sub-surface construction, brick or concrete hollow tile are better and cheaper materials.

Dimensions of Splicing Chambers. — The height of large splicing chambers is usually determined by the height in which a man can stand upright and is seldom less than 6½ feet. The width is similarly influenced by the space required to work in, which is about 4 feet. The length depends upon the length of splice and the space required to curve the cable from the ducts to the supporting shelves or racks, considerations which make a length of 8 feet the practical minimum where there are large cables.

Special chambers, such as those for bare grounded cables, for a small number of telephone or other small cables, may be made of smaller dimensions than stated above, because a man can work on his knees in a chamber 4 feet high and 3½ feet wide, and the length may be reduced to about 4 feet if the cables are small and flexible.

Table I gives the dimensions of standard splicing chambers used by several large traction and lighting companies. The letters refer to the dimensions on Figs. 3, 4, 5 and 6. The average volume of a splicing chamber is about 16 cubic feet per splice, although a maximum of 40 and a minimum of 6 are sometimes found.

Spacing of Splicing Chambers. — It is found that the greatest length of cable that can be pulled through a glazed tile conduit without injuring the cable or requiring special apparatus is about 400 or 500 feet on a straight or slightly curved run. Hence at distances of 400 or 500 feet along a conduit line it is

TABLE I. — DIMENSIONS OF SPLICING CHAMBERS

be pulled in and spliced. Local conditions and curves may prevent the full length being attained in all cases, but it is desirable to have no lengths greater than the standard, in order to avoid the necessity of keeping special long pieces of cable in stock.

Service Boxes. — Service boxes are usually iron castings similar in shape and size to an ordinary manhole casting, but provided with a completely waterproof inner cover which screws down on a gasket. The outer cover resembles that of a manhole. Inside the inner cover is a distribution board with copper bus bars, to which the main and feeder cables in the chamber connect through the bottom of the board.

Waterproofing and Drainage. — There is some diversity of opinion with regard to the value of waterproofing splicing chambers, although the modern tendency is to omit waterproofing and provide efficient drainage. Waterproofing is futile unless the duct lines leading to it are waterproofed. This is a very difficult and expensive process which seldom shows good results. Water will also enter chambers from the top and will be retained if the chamber is waterproof.

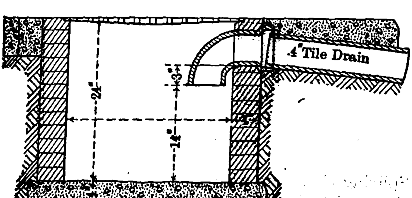

Fig. 7.

Every chamber should be provided with a sump into which the water can drain, Fig. 7. It is desirable to connect the sump to the sewer through a syphon and back-water valve. If this is not practicable the sump may be drained through the manhole by a hand pump.

Where natural drainage cannot be secured, as, for example, where the chamber is below the sewer level, it is good practice to provide a special drain pipe to which all the chambers are connected, the drainage being towards a general sump pit, which is kept

dry by an automatic sump pump. The cost of such a system often compares favorably with that of waterproofing, besides yielding superior results.

The sump of a splicing chamber should be covered with an easily removable grating; wooden ones are often used on account of their property of floating when the chamber is flooded, thereby leaving the sump open for the pipe of a hand pump.

Manhole Castings. — Manhole castings are usually made with two covers (Fig. 8), the outer of which should be made strong enough to stand the weight of the heaviest vehicle, and the inner should be as light as consistent with the rough usage they receive in handling. Both covers should be provided with means to grip them with a hook - bar. Where power cables are used it is essential to provide ventilating holes. It is usual to lock the inner cover with a substantial brass padlock with protected keyhole.

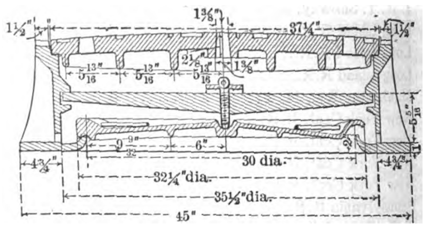

Fig. 8.

Cable Supports. — (*See also article on Wires and Cables, Insulated.*) Cables in splicing chambers are usually supported on iron brackets attached to the chamber walls. This construction is very satisfactory, especially if the power cables are properly wrapped with asbestos, but some engineers consider a shelf to be preferable, as it affords insulation and provides more protection between cables.

Concrete reinforced with expanded metal or wire cloth has proved satisfactory for shelves one inch thick, and is inexpensive. A good support for shelves is a pair of iron pins set in iron pipes, which are sunk in the chamber wall at a slight angle, so as to tilt the shelves toward the chamber wall as shown in Fig. 9.

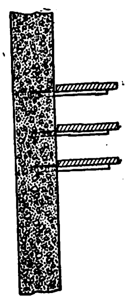

Fig. 9.

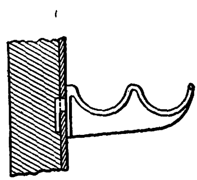

Fig. 10.

Splicing chambers with shelves have to be made larger and more expensive than those with duplex racks (Fig. 10), if an equal number of cables have to be carried.

Open-face conduits (Fig. 11) constitute a type of shelf which may be conveniently run all the way through a chamber to connect duct to duct. This gives excellent protection to the cables, but owing to the large size of the conduits,

used in a moderate-sized chamber is even more limited than where shelves are used.

RODDING AND WIRING OF CONDUIT LINES. — The only test which it is usual to apply to conduit lines is rodding with a mandrel in order to ascertain whether the ducts are continuous and unobstructed.

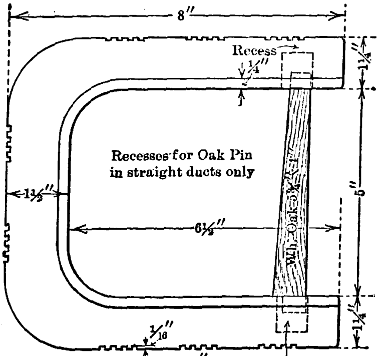

Fig. 11.

The rods used for this purpose are of hickory about one inch in diameter and three or four feet long and are fitted at the ends with steel couplings such as that shown in Fig. 12. The first rod is attached to a mandrel and pushed into the duct. Another rod is coupled to the first and the pair pushed further into the duct. By successively coupling other rods and pushing them into the duct, the mandrel is made to travel from one chamber to another. As soon as the mandrel emerges into the receiving chamber, the rods are pulled through and uncoupled. If an obstruction stops the mandrel an attempt is made to force it through by repeated blows, failing which, it becomes necessary to cut into the conduit line from the side.

Mandrels for Rodding. — Various types of mandrels are used for testing ducts, some hollow and smooth with sharp cutting edges, others fitted with numerous sharp projections and known as hedgehogs (Fig. 13).

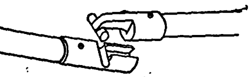

Fig. 12.

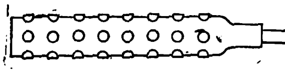

Fig. 13.

"Wiring" the Ducts. — It is usual to attach a galvanized steel wire (No. 10 or 12) to the last rod and leave the wire in the duct after the removal of the rods. The ducts may also be "wired" by the use of a conduit machine. This consists of a reel of steel tape and means for winding and unwinding the tape into the duct at the rate of about ten feet per second. This tape or "snake" having been pushed through the duct is pulled out again with the wire attached to its end.

SPECIFICATIONS FOR CONDUIT LINES. — (*See also article on Specifications.*) By far the greatest number of cable breakdowns occur from injury to the lead sheaths, either by electrolysis or by abrasions during installation. Sharp projections in the ducts should therefore be carefully guarded against, as a cable pulled over such a projection will have a groove cut along its entire length and the effective thickness of the sheath will be thereby materially reduced. The specifications for inspection and rodding given below are typical of the best modern practice, but unfortunately duct inspection is usually so lax that often in a large installation scarcely a single duct conforms in every particular with the specifications. Engineers are now beginning to realize the practical importance of giving each duct a rigid inspection, and rejecting those which have any

roughness or irregularity. Scarcely less important is rigid inspection during installation, in order to assure the most perfect alignment.

Details of Construction. — The following items should be covered:

Conduits. —

Single-way, or four-way.

Holes circular or square with rounded corners.

Maximum outside dimensions.

Minimum inside dimensions.

Minimum thickness of walls.

Shall be free from blisters, cracks and other imperfections which, in the opinion of the Engineer, will tend to injure the cables to be accommodated therein.

Shall be of good quality tile, thoroughly glazed inside and outside.

Shall be straight and true.

Shall be provided with holes for dowel pins if ducts are four-way. Dowell pins may also be called for.

The sides of single duct conduits shall be combed with two (2) sets of three (3) longitudinal combings each, each combing to have a width of one-quarter (¼) inch and a depth of one-sixteenth (1/16) inch. Multiple-duct conduits shall be scored transversely near the ends.

Conduits shall be of stated length. It is usual to call for a certain percentage of shorter lengths (generally 1 per cent), in order to finish runs or stagger joints. The permissible variation from the specified length should be stated.

(If fiber conduit is to be used, substitute the corresponding requirements.)

Cement. —

Shall be of approved brand.

Briquettes made of neat cement and kept one day in air and six days in water shall show a stated tensile strength. A corresponding strength may be similarly required of briquettes made of one part cement and two and one-half parts sand.

Shall be protected from moisture during work.

Sand. —

Shall be clean and free from loam or salt.

Shall be sharp and of stated coarseness.

Stone. —

Shall be of crushed granite, lime stone, trap rock or other approved variety.

Shall pass through a sieve of stated mesh.

Brick. —

Shall be of good commercial hard-burned sewer brick, or other stated variety.

Concrete. —

Stated proportions of cement, sand and stone. (Usually 1 part of cement, 2 parts of sand and 4 parts of stone.)

Maximum size of aggregate. (Usually ¾ inch.)

Sand and cement shall be mixed dry and wetted with only sufficient water to make a stiff paste. The stone having been previously wetted shall be added while wet and thoroughly mixed until all the stones are covered with mortar. It shall then be deposited as rapidly as possible. Machine-mixed concrete will be accepted if made in a

Cement Mortar. —

Stated proportions of cement and sand. (Usually 2½ to 1 of cement.)

Concrete mortar shall not be laid in freezing weather, and shall not be used after initial set has taken place.

Excavation. —

Shall always be of such depth as to leave a stated minimum distance between the top of the concrete over the conduits and the surface of the ground.

Ground on which conduits are laid shall be rammed solid before any concrete is laid.

Refilling Excavations. —

The best part of the material excavated shall be used.

Surplus material shall be carted away by the contractor (or will be carted away by the company).

Filling shall be thoroughly tamped and rolled, or flushed, as seems necessary to the Engineer, and shall be done in a manner to prevent, as far as possible, a settling of the earth after completion.

Obstructions. —

Obstructions encountered in the course of the work shall be overcome in a manner to be approved by the Engineer.

Laying Conduits. —

Shall be laid with ends square so as to leave a tight, well-fitting butt joint.

Joints shall be staggered horizontally and vertically.

Conduits shall be laid in a bed of cement mortar of about ¼-inch thickness.

Each joint shall be wrapped with two strips of burlap 6 inches wide and coated with neat cement mortar, the ends of the wrap to lap 4 inches. (It will insure more careful work if it be specified that the contractor shall supply rubber gloves to the men who lay the burlap.) Where conduits are laid on curves, the wraps shall be doubled if required to protect the openings between the ends of the conduits on the outside of the curve, and to exclude mortar from said openings. (This method of wrapping is not universal. If another method is to be used, corresponding details should be given.)

Conduits shall be laid with a mandrel of specified length and width and provided at the end with a rubber washer for wiping the joints.

Conduits shall be laid on a bed of concrete of stated depth, shall be covered at the top with a stated depth of concrete, and shall have a stated thickness of concrete on each side. Where the conduit line goes under railroad tracks, the concrete shall be suitably thickened and reinforced.

If conduits are four-way, they shall be laid with dowell pins at joints.

The alignment horizontally and vertically shall be satisfactory to the Engineer.

Drainage of Conduit Lines.— The grade of all conduit lines shall be such that water cannot stand in the ducts but shall drain into one or both splicing chambers.

Repairing. — All repairing shall be done in a manner satisfactory to the Engineer and the municipal authorities.

Extras. — No extras will be allowed the contractor for irregular work except

Rock blasting, if necessary.

Removal of pipes or other obstructions, if necessary.

Such work shall not be done without the consent of the Engineer. The contractor shall specify the cost of such work before it is begun.

Details of Terminals of Conduit Lines. — (Whether they go into power stations, etc.)

Splicing Chambers. — Shall be built according to plans supplied, unless local conditions interfere, in which case the suggested modifications shall be approved by the Engineer.

Chambers to be not more than a stated distance apart.

State any details pertaining to the design of the chamber and cable supports which may not be clear from the plans.

Tests. — The contractor shall notify the Engineer sufficiently in advance of the completion of the conduits to enable inspection at the factory to be arranged for.

Rodding, Cleaning and Wiring. — After the conduits are laid and the cement is sufficiently set, they shall be rodded and the contractor shall draw after such rods, wire brushes and a mandrel of specified dimensions. All mortar and other foreign matter shall be removed. If obstructions are found which cannot be removed by cleaners so as to pass the specified mandrel, the ducts shall be removed and relaid. Any expense incurred by such work shall be borne by the contractor. A galvanized wire of stated size shall be left in each conduit from splicing chamber to splicing chamber, and sufficient length shall be left at each end to permit it to be bent in order to prevent it from slipping into the duct.

Inspection. — During the process of construction, the Engineer reserves the right to inspect and the right to reject any and all parts which are not strictly in accordance with this specification.

INSTALLATION OF CONDUIT LINES. — The problems connected with the installation of conduits vary greatly with the local conditions. They involve the choice of trench excavation, drainage, removing or avoiding obstructions, concrete mixing and so on. The following details are gleaned from first-class examples of the various kinds of work described but should in no sense be regarded as standard.

Cross-country Conduit Lines. — The excavation for the conduit line of the American Telegraph and Telephone Company, between New York and Washington, was made partly by a trenching machine and partly by a trench plow. The trenching machine was of the Austin "caterpillar" type and dug a trench 18 inches wide and 3 feet deep at the rate of 3 feet of clean trench for each minute of actual working time. An engineer and two assistants were required to operate the machine, replacing, it is estimated, 50 laborers. Other sections were excavated by a trench plow drawn by two mules or horses, the furrow being made a few inches deeper at each pass, and the loose earth removed by shovelers. The conduit used in this installation was "pump-log" made of southern yellow pine 4½ inches square and 7 feet long with a circular duct 3 inches in diameter. These conduits were creosoted by the pressure process, with 15 pounds dead oil of coal tar per cubic foot of wood. Splicing chambers having concrete-block walls were built every 500 feet.

Conduit Lines for Railroads are usually difficult to construct and operate for the following reasons:

(1) Owing to the right-of-way being usually on made ground, excessive quantities of concrete and reinforcement are required to make a reasonably strong duct construction.

(2) Owing to the width of the right-of-way being usually very restricted it

(3) Owing to the vibration caused by heavy trains, it is necessary to bury the conduits at a greater depth, first to avoid undue stress on the conduit, and second to avoid crystallization of the cable sheaths.

In order to have the conduits below the frost level, the depth of ballast must be neglected, as it has been found that with stone ballast on top of the ground, the frost penetrates the ground about as far as if the ballast were not there, unless the ballast is very dirty.

(4) There is considerable difficulty in obtaining best results from labor where there are continual interruptions from trains. On a busy section a duct construction gang engaged for ten hours can possibly work two full hours.

(5) Owing to the right-of-way being often quite low, in many cases alongside of rivers, duct construction is likely to be seriously impeded by the flooding of trenches.

(6) Where the right-of-way shows signs of settlement, as, for example, on marshy ground, continuous piling is necessary to support the ducts. This involves the use of the track for construction purposes for long periods, and thereby not only impedes, but also endangers traffic.

(7) Duct-line construction generally involves interference with signal and interlocking apparatus, thereby introducing danger and expense.

(8) Bridge abutments, bridges, culverts, and in fact all special right-of-way construction, present complicated problems which can be solved only at great expense.

Conduit Lines in Cities. — The obstructions due to sewer, water and gas pipes, car tracks and foreign conduit lines, also render conduit construction in big cities a complicated problem. Plans made in the office can seldom be followed in the field, as the municipal pipe plans are seldom reliable, and the supervision of an experienced civil engineer is needed to solve the numerous problems which constantly arise. Excavation is almost invariably performed by hand labor, and when the conduits have been laid and covered with concrete, it is usual to lay a plank over them in order that future excavators may not drive picks into them. Obstructions are often avoided by changing the grouping of the conduits.

Laying Conduits. — Conduits must be laid so that joints are mechanically strong and the ducts unobstructed. With this in view joints should be staggered horizontally and vertically, and each joint covered with a wrapping impervious to mortar in bulk. Formerly the wrapping was omitted and the conduits joined with stiff mortar, but this became too expensive when the labor unions insisted upon the employment of masons for this work.

Single-duct Conduits are laid with their joints wrapped in a light-weight fabric saturated with thin cement mortar. In the Pennsylvania Tunnels, canvas weighing 10 ounces per yard was used, and cut into six-inch strips. Cheese cloth doubled has also met with favor. When laying conduits it is necessary to have a long mandrel (Fig. 14) to remove loose cement from the ducts. This mandrel is usually provided with a rubber washer at the rear, and a hook-eye at the front end. The conduit layer is provided with a hook rod by means of which he draws the mandrel after him as he lays the conduit.

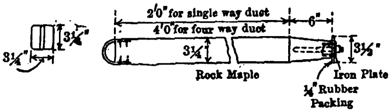

Fig. 14.

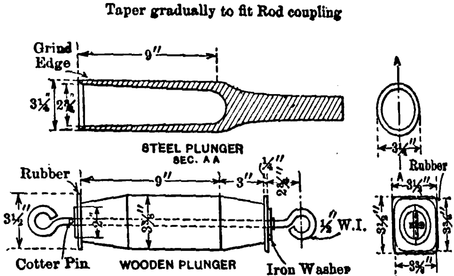
Four-duct Conduits are usually provided with holes for dowel pins by means of which the ducts are aligned. The joints are wrapped in burlap soaked in asphalt and afterwards painted with asphalt. No mandrel is used in this type of construction.

Concrete Covering. — However the conduits may be laid, the complete group is always inclosed in concrete to secure rigidity and protection, and the finished ducts are cleared of rubbish and obstructions by pushing a steel plunger through them by means of the rods described above. A steel plunger for this purpose is shown in Fig. 15, in which is also shown a wooden plunger with rubber washers, which should be drawn through the ducts to collect the loose particles left behind the steel plunger.



Steel Plunger, Steel Wire Flue Brush and Wooden Plunger to be passed through ducts in order named.

Fig. 15.

MAINTENANCE OF CONDUIT LINES. — The principal items of conduit-line maintenance are those relating to keeping the line clean and safe, namely, pumping out water, blowing out gas, removing mud, opening and closing manholes for the benefit of cable workers and inspecting the line to guard against theft and injury. Large systems have usually one or more wagons equipped with apparatus required for these purposes, and have men ready to go out with it upon emergency calls.

Removal of Water is usually the most important of operating troubles, especially where no drainage system is installed. When cable accidents occur, it is important to have the chambers accessible without delay and a portable pump is required. For this purpose a small gasoline or electric pump is useful, having a capacity of about 50 gallons per minute. Such a pump which has given good service is of the horizontal centrifugal type with horizontal discharge and costs about $200 complete with electric motor, hand priming pump and starting rheostat.

Ventilation does not occur naturally in conduit lines, because the cold air contained in them has no tendency to rise. Noxious gases therefore tend to accumulate in splicing chambers, endangering workers and making explosions possible. No permanent system of ventilation has proved successful, as it is found that pressure is maintained only at or near the blowing points. When it is necessary to blow out the chambers, it is therefore usual to employ a portable blower in conjunction with an air-tight false manhole cover.

Protection from theft of cable is secured (1) by locking the inner manhole cover and having the lock combination periodically changed; (2) by patrolling the line and (3) by using cable differing in some way from that used by neighboring companies, so that it can be easily identified if stolen.

Electrolysis is more fully treated in the article on *Electrolysis*. It should be noted that the prevention of electrolytic corrosion of cable sheaths depends more upon efficient drainage than anything else.

Maintenance of Conduit Lines Along Railroads present the following peculiar operating difficulties.

(1) Owing to the right-of-way being often on made ground, duct lines settle and crack, injuring the cables in them and preventing the removal and replace-

(2) Owing to the great depth of splicing chambers necessitated by railroad conditions, they are often full of water and cannot be cleared for repairs without pumping water out of as much of the system as is at the same level, a process which may take many hours to complete, possibly interfering with traffic during that time. Drainage is usually out of the question, owing to the absence of any kind of a drainage system below the surface system.

(3) The great depth of chambers requires the use of narrow chimneys connecting the chambers to the surface of the ground. This makes it almost impossible for employees to escape from chambers in case of trouble.

(4) Where improvements are made involving the raising of the right-of-way, as, for example, in eliminating grade crossings, ducts laid previous to the improvements become so deep that they are practically inaccessible for repairs and splicing chambers are correspondingly dangerous on account of their distance from the surface.

(5) The existence of water in low splicing chambers renders the cables particularly liable to electrolytic corrosion. This is a very serious matter where the grounded return is only a few feet away, as is almost invariably the case on a railroad. Electrolytic trouble cannot always be reduced by grounding the cable sheaths to the track rails, as such connections are seldom permissible where electric signals are used.

REPAIRS. — The principal repairs to conduit lines are those due to settlement and to damage done by adjacent building operations, such as the construction of sewers or railway tracks. It is sometimes desirable to replace the conduit line without disturbing the cables they contain. In such cases, the conduits are broken, the utmost care being taken to avoid injuring the cables. New conduits are then relaid on a firm foundation, after having been split longitudinally so as to fit over the cables. The whole construction is then rendered rigid by being inclosed in concrete.

COSTS. — The costs of conduit lines published from time to time are of merely local value, the labor of preparing a dry trench free from obstructions being an item whose variations are so great as to render insignificant the items of constant cost.

Mr. Quimby's table, given below, is probably representative of city practice, but conduit lines along railroads cost from 60 cents to $3.00 per duct foot, an average of 82 cents per duct foot having been obtained on a recent large railroad installation. In this case the labor item was about 80 per cent of the total although the construction was extremely solid and the number of ducts usually 20 or more in each trench.

The items to be considered in making an estimate of the cost of a conduit line are the following, the quantities all being per foot of trench.

Labor: excavating trench; excavating for splicing chambers; boxing and bracing; removing obstacles, such as gas and water pipes; mixing and placing concrete; placing conduit; carting and dumping; repaving; superintendence, outside; office expense.

Material: conduit; manhole and service boxes; covers, shelves, etc; sand, stone and cement; brick for splicing chambers (unless made of concrete); lumber for protecting top of ducts; lumber for bracing; incidentals.

The following table, adapted from that published by E. R. Quimby in the *Elec. World*, 1911, Vol. 57, p. 1294, includes all these items, and is based on actual cost of construction in New York City. Full details will be found in the original article. The figures given are for Belgian block pavement replaced and kept in repair for one year.

COST PER TRENCH FOOT OF CONDUIT LINE UNDER CITY STREETS

Estimates Based on Costs in New York City

a. Add 8 in. for thickness of pavement. b. Pipe at 18 cents per foot, tile duct at 6 ... feet. c. Service boxes every 55 feet. d. Splicing chambers every 260 feet.

Depreciation. — (*See also article on Depreciation.*) Conduit lines depreciate very slowly from the effects of deterioration or obsolescence. The rates given in the article on depreciation are based more upon guesswork than upon experience, as there are few conduit lines in existence which have lost much of their value from age unless unforseen circumstances have deprived them of some useful association upon which their value depended. The value of conduit lines often increases with age especially where they have been laid in growing districts, where the demand for duct space increases more rapidly than the supply.

CONTROL SYSTEMS FOR RAILWAY MOTORS. — (*See also Controllers; Motors; Railways, Electric Traction Systems for.*) The function of the control equipment is to regulate the speed and direction of the motors by certain definite systematic changes in connections. The speed of direct-current railway motors is controlled in two ways: (1) by connecting suitable resistances in series with the motors, which will reduce the voltage across the motors and thereby the current which they will take; (2) by changing the connection of the motors so that they will be connected at first in series, thereby applying half of the line voltage to each motor, and then in parallel across full line voltage. In most control equipments a combination of both methods is used. For the speed control of alternating-current railway motors an auto-transformer, or compensator, is used instead of the resistances.

The direction of rotation of the motors, d-c. or a-c., is changed by changing the direction of the current in either the fields or the armatures; it is customary to connect the terminals of each field coil to a reversing switch in order to accomplish this effect.

TERMINOLOGY. — The following terms are in general use.

Cylinder or Drum Control or Direct Control are names commonly applied to an equipment in which all the connections are made by contacts on a cylinder or drum which is manually operated by the motorman and located on the platform. This may, therefore, be called direct control.

Multiple-unit, Indirect, Remote Control or Train Control are names applied to an equipment in which the changes in connection of the main power circuit are made by switches called "contactors," usually located underneath the floor of the car, and controlled by electric circuits coming from a small master controller on the platform. There are two systems of multiple-unit control in use in this country, viz.,

Sprague-General Electric System. — In this system the contactors are closed by electromagnets which force a plunger against a spring, the latter normally holding the switch open.

Westinghouse "Unit Switch" System. — In this system the contactors are closed by compressed air, from the air-brake cylinders, the air valves at the switches being controlled electrically from the master controller.

Hand Control is a term applied to that method of control in which the motorman has it in his power to regulate the current to any value he pleases by moving the controller handle, the change in connections depending only upon the motion of the latter.

Automatic Control, as distinguished from hand control, is a type of control in which certain automatic devices prevent the motorman from causing the motors to take a current greater than a predetermined value. With this method of control the motors start with a definite current and as soon as the current has decreased to a specified value a change in the connections is automatically made. Thus the rate of acceleration and the current are kept practically uniform throughout the period of control. It is nearly always used in connection with multiple-unit control.

Rheostatic Control consists in connecting a resistance in series with the motor and short-circuiting consecutively parts of this resistance. It is seldom used at present, except on mining locomotives and for single motor operation.

Series-parallel Control, which is used on practically all railway equipments includes the feature of connecting two motors and their resistances in

tively until all resistance is cut out, under which condition the motors will operate efficiently at approximately half speed. On the next step of the controller the two motors with resistance in series are connected in parallel and subjected to full line voltage. There are three methods of accomplishing the change from series to parallel.

Transition with Power Off. — In the so-called type L controller power is entirely cut off from both motors while the change in connection is being made. This was formerly used for large-size motors and locomotives but is not at present much used.

Transition with Series Resistance. — During the transition from series to parallel a resistance is placed in series with one motor and the other motor is first short-circuited, then disconnected from the main circuit, and finally, placed in parallel with the other motor. This method is in general use in equipments of small motors with the so-called type K controller.

Bridge Transition. — The so-called "bridge" method consists in grouping the motors and their resistances like the arms of a Wheatstone bridge, so that after the two motors are in full-series position the resistances may be placed in circuit again in parallel with the motors, without opening the circuit; the two motors are then connected in parallel with each other and each in series with its own resistance. This method is preferable to either of the other two in that both motors are in operation throughout the whole control period. There is no noticeable jerk and it is not necessary to open the circuit, which would cause flashing at the switches. It is used in certain forms of the K control and in most of the multiple-unit control equipments, particularly for motors of large capacities and for locomotives.

Series-parallel Control with Four-motor Equipment. — Whereas the three methods just described apply particularly to two-motor equipments, they are equally applicable to four-motor equipments by connecting two motors permanently in parallel and treating them as a unit.

TYPE K CONTROL. — The type of control as well as the construction of the controllers for ordinary single-car equipments has been practically standardized in this country, the large manufacturers supplying control equipments which are practically identical. This type of control is known as the type K. The various sizes of type K controllers are listed in the table below.

Where type K controllers are used for motors of large capacity they are sometimes adapted with a modification of the remote control by the addition of two electrically-operated main switches placed underneath the floor of the car, the function of which is to open the main power circuit every time it is necessary that it should be opened and thus remove all flashing and arcing from the controller. This expedient makes it possible to use a smaller controller for a given capacity of motors and obviates all danger to the passengers from fire and fright. The scheme is accomplished by substituting for the main power circuit on the controller an auxiliary circuit carrying only one or two amperes and every time this auxiliary circuit is opened in the main controller the main switches underneath the car open the power circuit. When the auxiliary circuit is closed the main switches close the main circuit. By means of an overload trip operated by a coil in the main circuit these switches are also used as circuit breakers and if the current taken by the car exceeds a certain value a relay opens the auxiliary circuit which in turn causes the main switch to open.

Capacity and Weight of Type K Controllers. — The more usual forms of type K controllers and the capacity in motors for which they are adapted are as follows:

TYPE K CONTROLLERS

Designation	Number of motors	Total h.p.	Number of points	Weight, pounds*
K-10-A	2	80	5 series 4 parallel	940
K-10-H	2	80	5 series 4 parallel	
K-11-A	2	120	5 series 4 parallel	1020
K-11-H	2	120	5 series 4 parallel	
K-12-A	4	120	5 series 4 parallel	1175
K-12-D	4	120	5 series 4 parallel	
K-28-B	4	160	5 series 5 parallel	1350
K-28-F	4	160	5 series 5 parallel	
K-34-D	2 or 4	360	6 series 4 parallel	2250
K-34-F	2 or 4	360	6 series 4 parallel	
K-35-G	2 or 4	240	5 series 3 parallel	1800
K-35-M	2 or 4	240	5 series 3 parallel	

* Weight includes cables, etc., but not motors.

The 10 H, 11 H, 12 D, 28 F, 34 F and 35 M have auxiliary contactors for opening the main circuit.

The K 34 and K 35 have "bridge" transition. All others short-circuit one motor during transition.

The letter "B" in the designation of a controller indicates that it has contacts added to it to make it possible to operate electric brakes by causing the motors to act as generators to energize electric brake shoes, either of the axle or rim type.

Method of Operation of Type K Control. — The principle of the type K control for small and moderate-size motors is shown in Fig. 1. The controller has an operating handle which moves the main cylinder and thereby changes the connections, and also a reversing handle which moves the reversing cylinder. The latter merely changes the direction of the current through the fields of all the motors with respect to the armature. These two handles or cylinders are interlocked so that the reversing handle can only be moved when the operating handle is in the off-position, thus preventing reversal with voltage on the motors.

One terminal of one of the motors is grounded throughout. The first three points are known as accelerating steps. As resistance is in circuit for each of

length of time, for there is a considerable power loss in the rheostats and they are not designed for continuous operation. The fourth step, full series, is an efficient "running point," giving about half normal speed. The next two steps are transition steps and are not marked as points on the controller as they must be passed over rapidly. During this period one terminal of the second motor is grounded, thus short-circuiting the motor which has one terminal grounded initially; the connection between the two motors is then opened; finally the two motors are connected in parallel but in series with a part of the rheostat. If the controller is left on the transition point B the short-circuited motor may build up as a series generator and develop an excessive current. However, it takes an appreciable time for this to happen, so that any steady continuous movement of the controller will avoid the trouble. Points 5, 6 and 7 are accelerating steps with motors in parallel and resistance in series and are therefore not to be used continuously. At the last point the motors are in parallel, and all resistance is cut out; it is therefore an efficient high-speed running point.

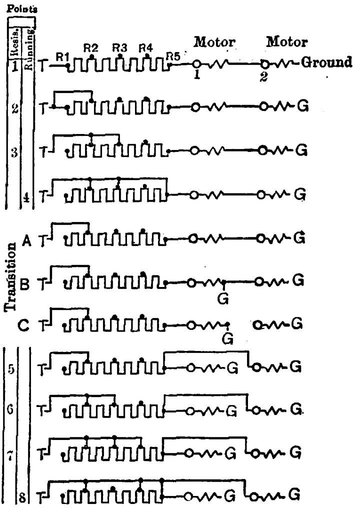

Fig. 1. Type K Control

In all controllers a magnetic blow-out and an "arc chute" are employed to interrupt the current quickly and direct it away from the contacts, in order to prevent short-circuiting other contacts. In the older types of controllers this was obtained from one large magnet coil and a large iron pole piece covering all the contacts. In the later forms each contact has an independent blow-out coil and small pole pieces. This gives a more powerful effect and more accurately directs the arc in the proper direction.

EFFICIENCY OF TWO- AND FOUR-MOTOR CONTROLLERS. — See *Railways, Energy Requirements for.*

REASONS FOR MULTIPLE-UNIT CONTROL. — When the total capacity of the motors on a car or locomotive exceeds 300 horse-power it is advisable, and when the capacity exceeds 400 horse-power it is necessary, to use the indirect or multiple-unit control, for the cylinder type of controllers required to handle the large currents become too bulky and dangerous to place on the platforms of passenger cars. The cylinder control is also inadequate when it is desired to control simultaneously the motors on the several cars in a train, which is necessary in order to obtain the high tractive effort necessary in high-speed service on elevated and underground railways.

For these two reasons the system of multiple-unit or train control was developed. As originally proposed by Sprague this consisted of a large cylinder controller on each car and each controller was actuated by a small motor instead of by hand. These small motors were controlled synchronously from a single point by means of auxiliary control circuits. With the growth in the capacity

of the motors this system became inadequate and was replaced by the systems now in use.

SPRAGUE-GENERAL ELECTRIC CONTROL. — There are two types in use, the type MK and the type MA. The chief difference in these two types is that the type MK is non-automatic whereas the type MA is provided

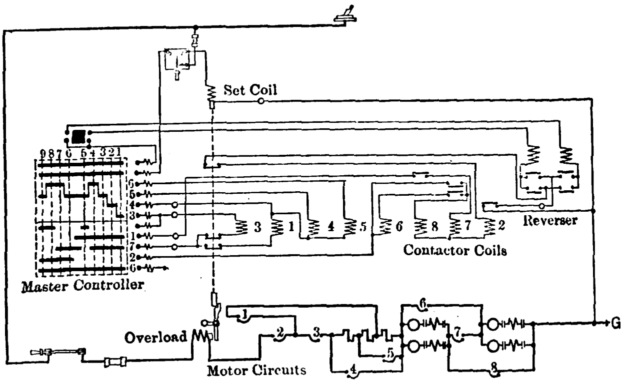

Fig. 2. Sprague-General Electric Type MK Control

with a current-limiting relay. Fig. 2 is a diagram of the type MK, showing the control circuits in light lines and the motor circuits in heavy lines.

The material included in the control equipment of a motor car consists of:

2 master controllers;
1 motor controller containing 8 or 10 contactors and a reverser;
3 master control switches;
1 main switch;
1 main fuse box;
1 set of rheostats;
Cables, Train Couplers.

Master Controller. — This is very similar to an ordinary railway drum-type controller but is much smaller, as the current carried by it is small. Each master controller is equipped with an operating handle, reversing handle, individual magnetic blow-outs and (optionally) a "deadman's handle," which automatically interrupts the current and applies the brakes when the motorman's hand is removed from the button located in the top of the handle.

Motor Controller. — This consists of an iron box lined with asbestos in which the several contactors and the reverser are placed, and is mounted under the car.

Contactors. — Each contactor consists of a powerful magnet operating an arm by means of a toggle joint against a spring pressure. This arm closes and opens the circuit in a strong magnetic field which acts as a blow-out. As one contactor can carry and break currents of several thousand amperes no extra circuit breakers are required. Each contactor is provided with interlocks in the form of relays so that contactor No. 2 cannot be operated until after No. 1 is closed, thus providing the proper sequence of operation under all conditions.

Reverser. — This is a switch with several circuits and contacts and is comparable to the reverser cylinder in an ordinary controller. These contacts are mounted on a rocker-arm actuated by two electromagnets, one for moving the switch to the forward and the other to the reverse position. The electromagnets receive their current from the master controller and are interlocked so that only one can be operated at a time.

Switches and Fuses in Control Circuit. — Motor cut-out switches are located on the reverser to permit cutting out a disabled motor. In the control circuit there is one main control switch and fuse to protect the control circuits, and near each master controller is located a "control and reset" switch, which in one position closes the circuit to the resetting coil of the overload relay in the main controller and in the other position closes the supply circuit for the master controller.

Main Switch. — A knife-blade switch is placed in the power circuit and is intended to disconnect the motor circuits from the trolley when it is desired to test the motor controller.

Train Couplers are provided where cars are to be operated in trains. These couplers or jumpers provide a means of connecting together similar control circuits of the different cars. They contain from 8 to 12 wires and are so designed that it is impossible to couple the cars together improperly.

Current-limiting Relay. — For automatic control, or acceleration at a predetermined current, a current-limit relay is provided on each car and this prevents each successive contactor from operating until the current in the motors has decreased to a predetermined value. On roads having a fairly level profile and operating with frequent stops this refinement is desirable, as it makes it possible for the motorman to accelerate the train every time at the maximum allowable rate and yet never exceed that rate except on a down grade. When this relay is provided the control equipment is known commercially as the type MA control.

WESTINGHOUSE "UNIT SWITCH" SYSTEM. — The Westinghouse multiple-unit control is known as "Unit Switch Control" and is designed either for the operation of several motor cars in a train or of single cars or locomotives, using either large currents or high voltage. There are four types of unit-switch control classified as follows:

Type H. L. — Hand-operated (non-automatic), using line voltage for the control circuits and having as many points on the controller dial as there are steps in the operation; also has a seperate reverser handle. One motor or group is short-circuited during transition from series to parallel.

Type A. L. — Automatically operated, using line voltage for the control circuits. The controller dial shows three points forward and three reverse, corresponding to switching, series running and parallel running, although there are more steps in the operation. Uses bridge transition from series to parallel.

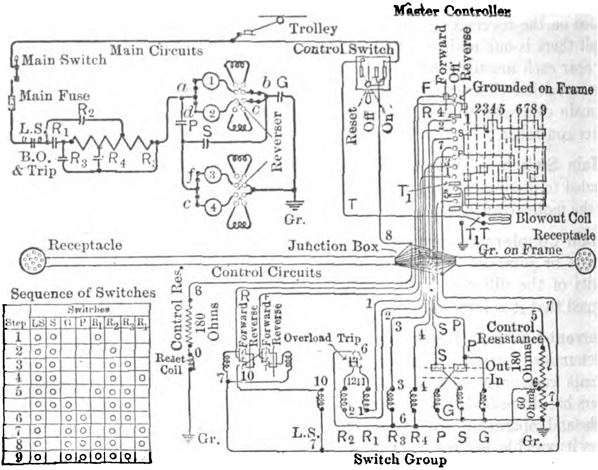
Type H. B. — Hand-operated, using current from a storage battery for the control circuits. Otherwise similar to the H. L.

Type A. B. — Automatically operated, using current from a storage battery for the control circuits. Otherwise similar to the A. L.

Operation of Type H. L. Control. — As typical of all of these classes the diagram in Fig. 3 shows the connections of the H. L. type for a four-motor equipment for either a car or a locomotive (*Cole, Electric Journal, Oct. 1912*),

As many as five motor cars per train may be operated by one man with this control system.

The main-circuit connections are made by means of a number of independent pneumatically-operated switches, known as unit switches, each provided with a strong magnetic blow-out and normally held open by a powerful spring. The overload trip that controls the opening of all switches in case of overload



Sequence of Switches

Step	LS	S	G	P	R_1	R_2	R_3	R_4
	Switches

7	o		o	o		o		o
8	o		o	o	o	o		o
9	o		o	o	o	o	o	

Fig. 3. Westinghouse, Type H. L. Unit Switch Control

or short-circuit is actuated by the magnetic pull produced by one of the blow-out coils, which is in the main circuit. When a predetermined current value is exceeded, a plunger carrying two contact discs breaks the control circuit, which causes certain switches to open in the line and switch group. This trip can only be reset when the controller is in the off-position.

A pneumatically-operated reverser controls the direction of operation of the car. This reverser consists of two pistons similar to those attached to the unit switches, which serve to move the reverser drum to forward or reverse position. The air-brake system furnishes compressed air for operating the reverser and switches.

A multi-conductor train line extends the length of each car and is tapped off at the master controllers and at the unit switch group to form the circuits needed. This train line is made continuous throughout a number of cars by multi-conductor jumpers between cars fitted into receptacles on each car. The current for the electromagnets which operate the valves of the unit switches is taken from low-voltage taps on a resistance connected across line potential.

Operation of Type A. L. Control. — The A. L. control differs from the hand-operated control in that the acceleration of the train is automatic. The master controller has only three positions, switching, series running and parallel running. The "off" position is in the center. The unit switches are provided with interlocks which are electrically connected with the valve magnet in such a manner that the closing of one switch energizes the magnet of the next, thus producing automatic progression of the switches, under the direction of the limit switch. This limit switch controls the rate at which the resistance

is cut out of circuit so as to give uniform accelerating current. The limit switch consists of a solenoid operated by the current of one motor or a pair of motors. When this current exceeds a specified limit for which the switch is adjusted, the circuit is opened through a pair of contacts in the operating circuit. The circuit remains open, so that no more unit switches can close until the accelerating current falls below the predetermined limit, when the control circuit is again closed and allows the unit switches to continue their progression.

SPECIFICATION FOR MULTIPLE UNIT CONTROL EQUIPMENT.* — The following memoranda are intended to assist in writing specifications for a complete equipment for the electrical control for a multiple-unit car or locomotive exclusive of motors and collecting shoes. See also article on *Specifications.*

Give a complete description of the service in which the equipment is to be used, including the maximum number and weight of cars or locomotives per train.

Similar motion of the master-controller handle shall always produce similar train motions.

A device shall be provided (this is optional) which will limit the rate at which the controller increases the motor voltage, and will assure even acceleration without surging, at the changes from series to series-parallel, and series-parallel to parallel, etc.

A relay shall be provided (this is optional) limiting the current to a specified maximum. (The use of such a relay is more usual on heavy, than on light, equipments.)

Provision shall be made so that acceleration can be arrested at any position by the master controller and so that the motor-circuit combinations shall never be beyond the position indicated by the master controller.

The controller shall automatically return to initial or open-circuit position when the general current supply fails, and when current is restored the control shall progress, as specified, to its former advanced position.

The reverser shall be interlocked so that it cannot be thrown when the motors are taking current.

The control apparatus shall operate satisfactory with a maximum line voltage of . . . . and a minimum line voltage of . . . . and shall never take a current exceeding . . . . amperes per car.

In the event of a train breaking in two, provision shall be made so that power shall be cut off from the detached rear portion without affecting the control of the front portion.

The master-controller handle shall be designed (this is optional) so that if the motorman releases it while operating a train, the power will be automatically cut off.

State whether controller is to be interlocked with air brakes.

Main circuit switch (for street cars only) shall be within easy reach of motorman at each end of car.

Each car or locomotive shall be provided with a control-circuit cut-out switch, which will enable the contactors on any car or locomotive to be disconnected from the control circuits.

Each car shall be provided with an automatic circuit breaker and devices for tripping it from any car of the train.

CAPACITY, WEIGHT AND COST OF CONTROL EQUIPMENTS. — The following table gives the capacity and weight and the approximate costs of some typical control equipments.

* By W. A. Del Mar.

Number of motors	H.P. of each motor	Type of control	Weight of control equipment, pounds	Weight of each motor, pounds	Total weight of equipment, pounds	Cost of equipment, dollars
4	25	*K*	1200	1900	8,800	1650
4	50	*K*	2200	2450	12,000	2400
4	75	*K*	2200	3200	15,000	3200
4	75	Multi-unit	2800	3200	15,600	3400
2	125	Multi-unit	2700	4150	11,000	2700
2	200	Multi-unit	3200	6400	16,000	3750

CONTROL OF HIGH-VOLTAGE D-C. MOTORS.—The motors operating on systems of from 1200 to 1500 volts are usually designed to operate two in series, thus each receives normally 600 or 750 volts. However, the insulation of each motor must be designed to withstand the whole line potential, and each motor must be able to withstand momentarily the line voltage across its commutator, for if one motor slips the voltage will be unevenly divided between them. For operation on high voltage two motors in series are normally treated as a unit and the series and parallel connection made with these double units. The multiple-unit control is preferable with these high voltages and contactors or unit switches similar to those for 600 volts are used. To operate the control it is customary to supply a self-starting dynamotor (q. v.) which provides 600 volts for this purpose as well as for the lights and other auxiliary apparatus.

Provision for 600-volt Operation. — Since these equipments usually operate also over 600-volt sections of road, provision has to be made to change the connection of the dynamotor when the transfer is made. If the cars are to operate at reduced speed on the lower voltages, as is usually the case on entering the city districts, no change need be made in the motor connections. But if the cars must operate at 600 volts at high speed over an interurban section, then provision must be made to separate the pairs of motors so that all motors will be in parallel for full-speed operation on 600 volts. This requires a commutating switch with automatic protection in order to provide that it is always changed when the car passes from one section to another.

2400-volt Systems.—For locomotive work 1200-volt motors are constructed to operate two in series on 2400 volts. The control for such a locomotive is similar to the control for a 1200-volt equipment.

CONTROL OF A-C. COMMUTATOR MOTORS.—A transformer or compensator is always used to transform the line voltage (3000, 6000 or 11,000 volts) to a voltage suitable for the motors, which is usually from 400 to 500 volts for two motors in series. Taps on the low-voltage side of the compensator (or auto-transformer) provide the various voltages necessary to start and control the motors and thus there is no need of series-parallel control or rheostats, and the energy lost in the rheostats is obviated. A compensator or auto-transformer is usually preferred to a transformer as it is lighter for a given capacity. It is usually placed in oil in a tank suspended from the bottom of the car body. Fewer steps (5 or 6 in all) are required for the control of a-c. motors on account of the reactance of the circuits. To avoid open circuiting the connection to the motors in changing from tap to tap or short-circuiting the portion of the transformer between the taps a "preventive resistance" is connected in the circuit momentarily during the transition. A reverser is provided to reverse the con-

The control may be either of the cylinder or multiple-unit type. In the former type a standard controller may be adapted for the work. If the multiple-unit control is used the cores of all the magnets and contactors must be of laminated iron and a special design of magnet used on account of the difference in characteristics of a-c. and d-c. magnets. In some a-c. multiple-unit equipments a storage battery is used to supply current for the control circuit, in which case d-c. electromagnets may be used in the contactors.

Provision for D-C. Operation. — For operation on direct current as well as alternating current provision must be made to perform the following operations: (1) cut the transformer out of circuit, (2) connect the motors for series-parallel control, (3) connect rheostats in circuit, (4) change the field connection of the motors, (5) change the connections of the compressor motors, (6) change the connections of the lighting circuits. All this is done by a "commutating switch" which is thrown over at the instant the change is made. This is so arranged that it can only be moved when the controller is at the off-position. The commutating switch is frequently operated automatically, so that when the car reaches a dead section of the trolley between the a-c. and d-c. sections, a no-voltage release throws everything to off-position and when the car reaches the new live section a "selector" coil moves the commutating switch to the proper position.

CONTROL OF THREE-PHASE INDUCTION MOTORS. — Three-phase induction motors for railway work may be controlled by three methods, viz: (1) Changeable pole windings, (2) concatenation of two motors, (3) variable resistance in secondary.

The first two methods were given a considerable trial by German manufacturers some years ago, and have been practically abandoned on account of their complications. In addition to their complications the variable resistance method must also be used with them to provide the smaller gradations of speed.

Variable-resistance Methods. — The secondaries of the motors have a definite winding and the terminals are brought to collector rings by means of which a three-phase starting resistance is connected into the circuit. The speed of the motors is controlled by varying this resistance. Under these conditions the operating characteristics of the motors are similar to those of a d-c. shunt motor. At all fractional speeds a considerable amount of energy is wasted in the rheostats and there is only one efficient running speed. For prolonged running at fractional speed the rheostats must have considerable heat-dissipating capacity. To reverse the direction of the motors a reverser is employed which reverses the connections of two of the three primary leads on each motor. Either the cylinder or multiple-unit control may be used. With induction motors it is desirable to provide a separate set of resistances for each motor to avoid the tendency of the motors to exchange current and "buck," which would occur if the driving wheels were not of exactly the same diameter and one set of resistances were used for all motors. With several induction motors on one car it is desirable to accurately maintain the same diameter of driving wheels on all axles in order to divide the load equally between the motors.

[W. I. SLICHTER.]

CONTROLLERS. — (*See also Control Systems for Railway Motors; Regulators; Rheostats; Switchgear Equipment for Power Stations.*) Any device for regulating the current or voltage of an electric circuit may be called a controller. Various kinds of controllers have been given different names by users and manufacturers.

DEFINITIONS. — To avoid confusion the various names are used throughout this book as defined below.

Compensator or Induction Starter, an auto-transformer for supplying reduced voltage to the terminals of an induction motor during acceleration; see *Starters, Motor.*

Controller, any device which controls the running speed of a motor. This article deals only with controllers as here defined. A controller frequently combines starting with running features; see *Starters, Motor.*

Regulator, any device for adjusting the voltage of a circuit. A compensator is a special form of regulator. The term regulator is sometimes reserved for devices which utilize inductive action for their control properties; such a device will be designated specially as a potential regulator; see *Regulators.*

Rheostat, the resistance portion of a controller or starter, through which flows the main current of the circuit whose voltage is controlled. A field rheostat is any device employing a variable resistance to control the voltage across the field windings of a generator or motor. The field rheostat of a d-c. motor indirectly controls the speed, because it controls the voltage and current of the field winding; see *Rheostats; Starters, Motor.*

Starters, Motor, a resistance or auto-transformer used with a motor, either d-c. or a-c., to limit the starting current; see *Starters, Motor.*

CONTROLLERS FOR DIRECT-CURRENT MOTORS are usually operated by varying the resistance in the armature or field circuits of the motors, if the motors run separately, or by various groupings of motors in series and parallel, where the motors are in pairs, as in the usual railway practice.

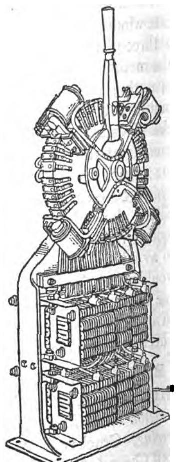

Fig. 1. Grindstone Controller

"Grindstone" Type of Controller (Fig. 1). — One of the simplest types of controllers is the so-called "grindstone" controller shown in Fig. 1, which is ordinarily furnished for series-wound d-c. crane motors. The movable-finger contacts are mounted on a four-arm spider. The connections are so made that moving the arm in one direction will mean clockwise rotation of the motor, and movement from the off position in the opposite direction will mean counter-clockwise rotation. The amount of movement controls the amount of resistance in the armature circuit and consequently the speed of the motor.

In controllers of this type all wearing parts, contacts and finger tips are extremely simple and inexpensive and readily renewable so that the maintenance charge is kept down to a minimum. In the smaller sizes the contacts are mounted on a flat soapstone face plate with a single magnetic blow-out coil centrally located to prevent injurious arcing. For larger sizes, such as illustrated in Fig. 1, four sets of copper contacts are arranged on the periphery of a circular soapstone disk in

is provided with a blow-out coil and in some cases an auxiliary switch is provided for use with a brake magnet when the contact arm passes to the off position.

Drum Type of Controller (Fig. 2). — Another type of controller in common use is the drum controller, such as shown in Fig. 2. Drum controllers are used with machine tools for varying the speed and reversing the direction of rotation of adjustable-speed d-c. motors by means of armature and field resistance. On the larger sizes magnetic blow-outs are used. The controller illustrated is shown with its cover removed and is provided with two dials, one connected with the armature resistor and one with the field resistor. In the smaller sizes these resistors are inside the controller and in larger sizes they are outside.

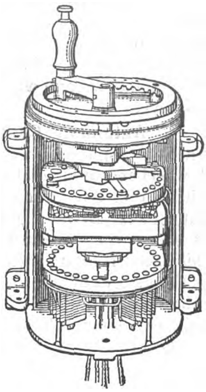

Fig. 2. Drum Controller (cover off)

Series-Parallel Controllers. — A familiar type of drum controller is the series-parallel controller in general use on street cars for the control of two or four d-c. series-wound motors. To keep down the starting current and to provide an even rate of acceleration, the first position of such a controller connects resistance in series with all of the motors, which are themselves connected in series in pairs. The resistance is cut out in steps until the two motors or two pairs of motors are in series without resistance, when the car is running at approximately half speed. The motors are then changed to the parallel arrangement with resistance in series with each motor. The resistance is again cut out in steps until the motors are all operating in parallel and the car is running at maximum speed. Occasionally provision is made for shunting the series fields of the motors for still higher speed. Controllers of this type are almost invariably provided with magnetic blow-outs, reversing switches, motor cut-outs and various mechanical interlocks that prevent passing from series to multiple connection if a motor is cut out, prevent operating the main drum if the reverse handle is in the off position, etc. Such controllers are frequently provided with brake attachments and are made as fool-proof as possible. (*See also Control Systems for Railway Motors.*)

Master Controllers. — Drum controllers are also used as master controllers with contactors to secure starting and speed regulation of large a-c. and d-c. motors, as well as the multiple-unit control of motor cars or locomotives on railway service.

CONTROLLERS FOR INDUCTION MOTORS. — Controllers with squirrel cage secondaries usually operate by connecting the motors to various voltages obtained from transformer taps. If the motors are provided with wound secondaries the controllers frequently operate by varying the resistance in the secondary circuit. The resistors must then be designed to carry the running current of the motor continuously without overheating (*see Motors, Polyphase Induction; Starters, Motor*).

With a reversing motor, as in crane or rolling mill service, a similar method of control is used except that the controller is provided with two drums which are operated by a single handle. The motor will run in one direction when the handle is turned to the right, say, and in the reverse direction when it is turned to the left. In going from the off position the first step connects the primary circuit of the motor to the line and subsequent steps cut out the secondary resist-

ance. In passing from full speed in one direction to full speed in the other the resistance is all cut into circuit before reversing. In the off-position the motor is entirely disconnected from the line.

Use of Contactors with A-C. Controllers. — For reversing, mill or hoisting work using induction motors with wound secondaries many very ingenious and highly satisfactory installations have been put in service which use solenoid-operated magnet switches, or contactors, for the secondary and occasionally for the primary circuits. These are worked from a master controller or similar device, or are operated automatically by the positions of the rolls, hoist, etc. Automatic acceleration can be obtained in the same manner as with direct-current motors and various safeguards, such as dynamic breaking, can also be employed.

Automatic Control of Input to Flywheel Motor-generator Set. — Another application for contactor control with automatic features is with flywheel motor-generator sets which use a very heavy flywheel in connection with a d-c. generator and an a-c. motor with wound secondary. The power put into the flywheel or delivered up by it depends upon the variation in speed of the motor generator. By varying the resistance in the motor secondary this speed regulation can be secured. By the use of suitable relays the input to the motor and consequently the load on the a-c. system can be kept practically constant, while the output of the d-c. generator supplying power to a d-c. hoist or rolling-mill motor is undergoing wide fluctuations, the energy in the flywheel taking care of the difference between the constant input and the variable output. See also article on *Flywheels for Load Equalization.*

COST OF CONTROLLERS. — The following figures will serve as a rough indication of the cost of various sizes and types of controllers. Costs of controllers vary through wide limits depending upon the design, the amount of speed variation desired, etc.

COST OF CONTROLLERS FOR 500-VOLT MOTORS*

Horse-power of motor	5	25	50	100	150
Grindstone type (Fig. 1)	$105	$110	$115	$170	$200
Drum type (Fig. 2)	52	70	100	....	....
Reversing controllers for wound secondary induction motors, 2 to 1 speed range	....	90	140	235	357

* Controllers for 110- or 220-volt motors cost about the same as for 500-volt motors.

[S. Q. HAYES.]

CONVERTERS, SYNCHRONOUS OR ROTARY. — (*See also Generators, Alternating-current; Generators, Direct-current; Motor Generators; Motors, Synchronous; Transformers; Substations, Railway.*) Since in general it is more economical to transmit electrical energy in the form of alternating currents and more convenient to utilize it in the form of direct currents, some means of converting from one form of electrical energy to the other is desirable. For this purpose synchronous converters and motor-generator sets (q.v.) are available. Synchronous converters are also called "rotary converters."

A synchronous converter is a machine very similar to a d-c. generator in which certain commutator segments, or the conductors connected to them, are connected to 2, 3, 4 or 6 collector rings as the case may be. When the movable member is caused to rotate, the voltage between any two collector rings is alternating. Such a machine, when driven by an engine or motor, may be operated as an a-c. generator or as a "double-current" generator giving alternating current from its collector rings and direct current from its commutator. If the collector rings are connected to a source of alternating currents the machine will run as a synchronous motor and direct current may be obtained from the brushes on the commutator; i.e., the machine, with but one set of windings acts simultaneously as an alternating-current motor and a direct-current generator. It has therefore the friction, core-loss and excitation loss of one machine instead of two, and since the motor and generator currents flow in the same winding and during at least the major part of each cycle are in opposite directions, they more or less balance each other and the armature RI^2 loss is much less than in either a motor or generator alone.

Synchronous Converter versus Motor Generator. — A converter is much more efficient and weighs and costs less than a motor-generator set of the same capacity. It also occupies less space. However, since only one winding is used, there is a definite relation between the e.m.f's. of the a-c. and d-c. terminals. The maximum value of the alternating wave bears a definite relation to the direct e.m.f. (*see below*). It is therefore necessary to supply the converter with a voltage of the same order as the direct voltage and this involves the use of transformers, if a high-voltage transmission line is used to supply the converter. Motors operating at voltages as high as 13,000 volts can be used in motor-generator sets.

Relative Efficiencies. — The efficiency of a converter is in the neighborhood of 93 per cent and of the transformers 97 per cent, thus the efficiency of the combination is about 90 per cent. The efficiency of a synchronous motor is in the neighborhood of 93 per cent and of a d-c. generator 92 per cent, thus the combination motor-generator set has an efficiency of 85.5 per cent. If the supply voltage is greater than 13,000 volts, transformers will also be needed for the motor-generator set and the net efficiency would then be 83 per cent.

Synchronous Converter versus Rectifiers. — A converter differs from a rectifier (q.v.), since the former gives a direct e.m.f. of constant and uniform value and the latter gives a pulsating unidirectional voltage and current. In the former the energy is stored in the form of magnetism for an instant whereas in the latter there is no magnetic field and no storage of energy. A rectifier will not work on an inductive d-c. circuit but a converter will.

APPLICATION OF CONVERTERS. — The most common application of synchronous converters is in electric railway work. The great majority of motors for electric traction are direct-current series type, operating at from 500 to 600 volts. The energy for these motors must be transmitted over long distances, which requires a high voltage a-c. transmission line and converters to link the d-c. distribution with the a-c. transmission.

TERMINOLOGY. — The following terms are used to describe certain characteristic features of the various kinds of synchronous converters.

Phases and Rings. — A single-phase converter has two collector rings and each ring is connected to the windings by as many equally spaced taps as there are pairs of poles. The taps for the two rings alternate at equal spaces. A single-phase converter is therefore a two-ring converter.

A three-phase converter has three rings and three equally spaced taps (one for each ring) for every pair of poles. A four-phase or quarter-phase converter has four rings and four taps for every pair of poles. A six-phase converter has six rings and six taps per pair of poles.

Shunt and Compound-wound Converters. — A converter may be shunt or compound wound, depending upon the service for which it is intended. The series winding is intended to make the converter take leading current when the load increases and thus increase the voltage at the a-c. terminals, but the ratio of the a-c. *terminal* voltage to the d-c. voltage remains unaltered.

Inverted Converter. — Sometimes a converter is operated to convert from d-c. to a-c. It is then called an "inverted converter." The machine will operate satisfactorily in this manner, but its speed depends upon the nature of the a-c. load. An inductive load in the a-c. circuit causes the armature to demagnetize the fields, with a resultant increase in speed. It is therefore dangerous to operate an inverted converter on an inductive load unless it is provided with a speed-limit device. This effect does not occur when the machine is operating as an a-c. motor, since its speed is fixed by the frequency of the supply circuit.

Motor Converter. — This is a combination of an induction motor and converter connected in series or concatenation (*see Motors, Induction*). The converter receives half the power in mechanical form from the shaft and half the power inductively, in the form of alternating current at half frequency, from the secondary of the induction motor. By this means the steadiness of a 30-cycle converter is obtained in a 60-cycle unit.

Split-pole Converter. — The "split-pole" or "regulating-pole" converter is designed to give a variable ratio of alternating e.m.f. to direct e.m.f., for operation in parallel with storage batteries and similar purposes. The field poles are divided into sections which may be assisting or opposing each other magnetically. This changes the shape of the flux distribution, which in turn changes the wave shape of the counter e.m.f. and thus the ratio of d-c. (maximum) to a-c. (effective) voltage is changed.

Converter with Series Booster. — A synchronous converter with series booster is sometimes used for purposes similar to those of the regulating pole converter. It is merely a converter with a separately excited a-c. generator on the same shaft as the converter, and the armature of this generator is connected in series with the converter armature and the line. This generator acts as an a-c. booster and raises the line voltage.

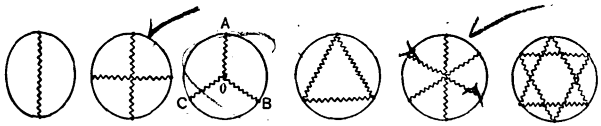
RATING AND PERFORMANCE. — The manufacturing companies have up to the present (1914) divided synchronous converters into classes for purposes of rating according to their overload capacity in the same manner as a-c. generators (q.v.) are classified. Twenty-five-cycle converters will give a considerable overload without injurious sparking at the commutator, but 60-cycle converters are more sensitive to overloads. Certain 25-cycle railway converters will give three times normal output momentarily without damage. For the new A.I.E.E. ratings see *Standardization Rules*.

PRINCIPLES OF CONVERTER ACTION. — In this section are briefly treated those features ... in which the converter

differs in action from an a-c. or d-c. generator; see table on page 284 for a summary of the voltage, current and capacity relations.

Connections and Voltage Ratios. — The ratio of voltage on the a-c. side to that on the d-c. side depends upon the number of rings and type of connection employed.

Two-ring Converter. — The two collector rings are connected by taps to the same winding as the commutator; hence the alternating e.m.f. has the same value as the direct e.m.f. at the instant that the taps pass the brushes. As this is also the maximum value of the alternating e.m.f., the effective value (i.e., the value to be indicated by a voltmeter) will be 0.707 times the maximum or 0.707 times the direct e.m.f. Fig. 1 shows in a simple manner the connection of a single-phase converter. The external circle represents a two-pole arma-



Figs. 1 2 3 4 5 6

Transformer Connections and Vector Relation of Voltages in Synchronous Converter

ture winding and inside is shown the supply transformer connected to two taps diametrically opposite each other. The voltage across this transformer would be 0.707 E, where E is the voltage between the positive and negative brushes on the d-c. side.

Four-ring Converter. — If two additional collector rings are connected to conductors spaced half way between the former taps, there results the quarter-phase converter shown in Fig. 2. The voltage across each supply circuit or transformer is the same as before, but the two voltages will differ in phase by 90 degrees.

Three-ring Converter. — If three collector rings are connected to taps spaced 120 degrees apart the e.m.f. between adjacent collector rings will be the vector sum of AO and OB in Fig. 3. Since AO and OB each equal $0.5 \times 0.707\,E$ the voltage AB will be $\sqrt{3} \times 0.5 \times 0.707\,E = 0.612\,E$. Thus in a three-ring or three-phase converter the voltage between adjacent taps is 0.612 times the direct voltage and the connections of transformer are as in Figs. 3 and 4.

Six-ring Converter — Diametrical and Double Delta Connections. — A six-ring converter may be connected diametrical as in Fig. 5 in which case the voltage of each transformer will be $0.707 \times E$ and the result will be like the combination of three single-phase groups. A six-ring or six-phase converter may also be connected "double delta" as shown in Fig. 6, which is similar to the combination of two groups of three-phase delta transformers. In both cases the voltage between adjacent taps of a six-phase converter is $0.355\,E$.

n-Ring Converter. — In general the voltage between taps of any converter having n equally spaced taps per pair of poles is

$$E_{ac} = \frac{E \sin \frac{\pi}{n}}{\sqrt{2}}.$$

Current Ratios. — To determine the ratio of the continuous current I to the alternating current I_3 per collector ring in a three-phase converter, for example, assume the d-c. output equal to the a-c. input with unity power factor; then

$$\sqrt{3}\, E_3 I_3 = EI,$$

and, from preceding paragraph,

$$E_3 = 0.612\, E,$$

where E_3 = a-c. voltage between lines; I_3 = alternating current per line; E = direct voltage; I = direct current. From these two relations

$$I_3 = 0.94\, I.$$

The ratios of currents for other converters are obtained similarly, and are given in the table on page 284.

In actual practice the current on the input side must be greater than that given by these relations, in order to supply the losses in the converter, and the alternating current will also vary inversely as the power factor, which is taken as unity in the table.

Resultant Coil-Current. — In any machine acting simultaneously as a motor and a generator the two currents must flow in opposite directions, and the current in any particular conductor will be the difference between the two. In any particular coil the direct current is constant in amount and direction from the instant the commutator segment connected to this coil passes the positive brush to the instant it passes the negative brush, and conversely from negative to positive brush. In any coil midway between the a-c. taps the alternating current is a maximum when this coil is half way between brushes (for unity power factor), and the current falls to zero as the coil reaches the interpolar position. Therefore, for the period of time that the direct current in a coil remains constant in amount and direction there is also in it a variable current changing from zero to a maximum and back to zero again. The net or resultant current will therefore have a wave shape and frequency somewhat as shown at R in Fig. 7. The heating in this particular coil will therefore be proportional to the product of the resistance of the coil by the square of this current, and it is readily seen that the power lost is less than that due to either the direct or alternating current alone.

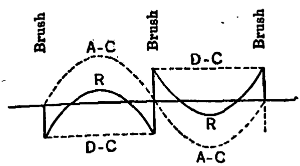


Fig. 7. Current in Coil Midway between Taps

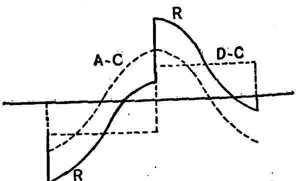

Fig. 8. Current in Coil at Tap in Two-ring Converter

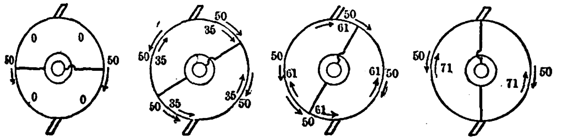
A coil situated very near one of the a-c. taps will carry a direct current subject to the same law as before mentioned, but the alternating current in this coil is the same as that in the middle coil and has its maximum value when the middle coil is at the middle of the poles and not when this particular end coil is at the middle of the pole. The alternating current in this coil may therefore reach its maximum value soon after the coil has passed a brush, as shown in Fig. 8, and the resultant of the two currents is greater than that in the middle coil. The further a coil is situated from the middle coil of a group, the greater is the phase displacement of its alternating current, the greater is the value of

the resultant current and the greater is the heating effect. Thus although the heating effect in a rotary converter winding is less than that of a direct-current machine having the same output it is different in each and every coil, is minimum in the central coil (when the power factor is unity) and is maximum at the coil nearest the tap, and the greater the angle between taps the greater is the total heating effect.

Distribution of Heat Losses in Armature Winding.—In Figs. 9 to 12 inclusive, representing a two-ring converter, the numbers outside the circle



Figs. 9 10 11 12

Component Currents in a Two-ring Converter

represent the direct current in the winding (corresponding to 100 amperes in the external d-c. circuit and unity power factor on a-c. side) and the numbers inside the circle represent the alternating current in the winding. It will be seen that the resultant current in a coil midway between taps, Fig. 9, never exceeds $50 + 0 = 50$ amperes. A coil 30 degrees on one side of the middle coil, Fig. 10, has a maximum current of $50 + 35 = 85$ amperes, a coil 60 degrees from the middle, Fig. 11, has a maximum current of $50 + 61 = 111$ amperes, and a coil 90 degrees from the middle, Fig. 12, has a maximum current of $50 + 71 = 121$ amperes. The heating of the armature winding is therefore not uniformly distributed, though the conduction of heat from one part of the winding to the other tends to equalize the temperature rise.

If the converter operates at a power factor different from unity, the position of minimum resultant current is no longer at the middle coil, but is moved one way with leading current and the opposite way with lagging current. Thus one end coil has improved heating conditions, and the middle coil and the other end coil have much worse heating conditions, the result being that the heating as a whole has increased and is more non-uniformly distributed than with unity power factor.

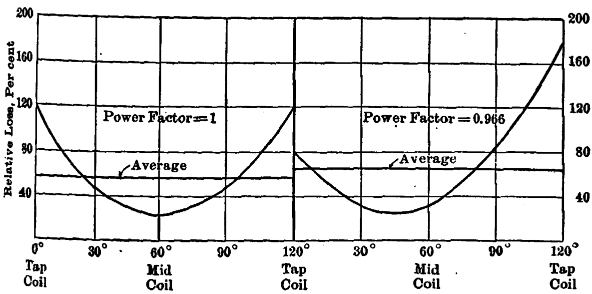


Fig. 13. Relative RI^2 in Individual Coils of Three-ring Converter

The power lost in each individual coil of a converter and the effect of the power factor on this loss is very well shown in Figs. 13 and 14, taken from a

paper by J. E. Woodbridge (*A.I.E.E., 1908*). In Fig. 13 the curved line shows the relative RI^2 loss in a coil having any position throughout 120 degrees of one phase of a three-phase converter when the power factor is unity. The

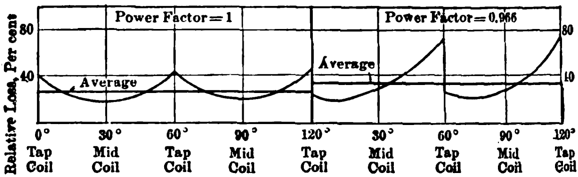

Fig. 14. Relative RI^2 in Individual Coils of Six-ring Converter

curve shows the ratio of the loss compared to the loss in the same machine acting as a d-c. generator of the same capacity. It will be noted that the middle coil has a loss of 22 per cent of that of the generator and the end coils 120 per cent, and that the average loss is 57 per cent. For a power factor of 0.966, representing a phase displacement of current of 15 degrees, the loss in individual coils ranges from a maximum value of 180 per cent at one tap to a minimum value of 22 per cent in the coil shifted 15 degrees to one side of the middle coil. The other end coil has a loss of a little over 80 per cent of the generator loss. The average value has been increased to 65 per cent.

In Fig. 14 the same ratios are shown for a six-phase converter, in which the winding of one phase is distributed over only 60 degrees. Consequently the conditions are better and the maximum loss due to low power factor is less.

Dependence of Output upon Number of Phases. — As a result of these conditions we have the following relations of the capacity of a given armature with various numbers and connections of taps, the capacity being based on an equal total amount of RI^2 loss.

It should be remembered that there are other losses besides coil losses in the converter, and that therefore practical figures are slightly different from those given in the table.

VOLTAGE, CURRENT AND OUTPUT RATIOS

	D-C. generator	Converters					
		2-ring	3-ring	4-ring	6-ring diametrical	6-ring double delta	12-ring
D-C. volts	100	100	100	100	100	100	100

Relative RI^2 loss	100	137	55	37	26	26	20
Relative output:							
Unity power factor	100	85	134	165	197	197	224
87 per cent power factor	...	...	99	115	129	129	135

Field Excitation. — The variation of the field excitation of a synchronous converter has much the same effect as in the case of a synchronous motor (*see Motors, Synchronous*); that is, if its field is under-excited the armature will draw a lagging current which assists the field and sets up the necessary flux, whereas if the field is over-excited, the armature will draw a leading current which opposes the field and reduces the flux. By this means the converter may be made to take either a leading or lagging current. A leading current flowing over a line having inductance tends to raise the voltage at the receiving end of the line.

Line Compounding. — If there is sufficient leading current and sufficient inductance in the line, the voltage at the receiving end may be greater than at the sending end in spite of the resistance of the line. This is sometimes called "line compounding." The relation between the voltages at the two ends of the line may be expressed as follows:

Let

E = voltage to neutral at sending end;

V = voltage to neutral at receiving end;

I_1 = component of line current in phase with V, i.e., the power component of the line current;

I_2 = component of line current at 90 degrees to V, i.e., the *leading* reactive component of the line current;

r = resistance of one line;*

x = inductive reactance of one line;*

then, noting that I_2 is to be taken positive when leading,

$$E^2 = (V + rI_1 - xI_2)^2 + (xI_1 + rI_2)^2.$$

Use of Series Field. — In practice a series field is added to the converter and the shunt excitation is adjusted so that the armature current is lagging at no load. As the load increases the series field increases, the adjustment being such that at about ¾ load the proper excitation for unity power factor is given. Hence at all loads over ¾ the field will be over-excited, the current will be leading and the voltage will be raised or compounded.

DESIGN. — The design of a synchronous converter is very similar to the design of a d-c. generator (q.v.), except for certain special conditions due to the fact that the frequency is fixed by the frequency of the supply system, and that greater latitude is allowed in the choice of the nominal value of the d-c. armature reaction and copper density, because the real value of these quantities is the difference between their nominal d-c. values and their a-c. values.

Speed and Number of Poles. — The revolutions per minute and the number of poles are definitely related to the frequency of the supply circuit, in cycles per second, in accordance with the formula:

$$120 \times (\text{frequency}) = (\text{number of poles}) \times (\text{rev. per min.}).$$

The choice of the number of poles usually depends upon the commutator.

Commutator. — The design of the commutator is usually the limiting feature and therefore the first to be considered. This is particularly true of either high-frequency (60 cycle) or high-voltage (600 volt) machines. Three factors must be considered in the design of the commutator to secure successful commutation and life of the commutator, namely, peripheral speed, voltage between bars, thickness of bars. If the peripheral speed or the voltage between

* r and x should include respectively the resistance and reactance not only of the line wire, but also the transformers and reactance coils through which the line current passes.

bars is too high commutation will be bad. If the commutator bars are too thin the commutator will not retain its shape and commutation will be bad. These three limiting factors are very closely related and in a high-voltage machine give very little choice. The diameter of the commutator depends upon the voltage and frequency, and its minimum value is given by the three following relations. Let

s = pitch of commutator bars in inches. This ranges from 0.15 in small machines to 0.20 in high-voltage or high-frequency machines, to 0.40 in liberally designed machines. These values include the width of bar and about 0.03 inch insulation between bars.

V = peripheral speed of commutator in feet per minute. This ranges from 3500 in liberally designed low-voltage, 25-cycle machines to 5000 in 60-cycle machines, and is extended to 6000 under compulsion.

e = average volts per bar = machine voltage divided by the number of bars between brush studs. Normal values are from 8 to 14. The maximum voltage between bars is about 1.57 times this.

f = frequency in cycles per second;

E = voltage between d-c. terminals;

p = number of poles;

n = total number of commutator bars;

d = diameter of commutator in inches.

Then

$$s = \frac{Ve}{10Ef}, \qquad n = \frac{pE}{e}, \qquad d = \frac{sn}{\pi}.$$

Armature Ampere Turns and Current Density. — Since the d-c. and a-c. armature reactions are opposed to each other the nominal value of the d-c. armature reaction ampere turns may be chosen much higher than in generators and values of from 4000 to 8000 ampere turns per pole are in common practice. The nominal or apparent value of the ampere conductors per inch of periphery varies from 500 to 900, and the apparent current density (d-c.) in the armature copper from 2500 to 5000 amperes per square inch.

Diameter of Armature. — The diameter of the armature per pole varies from 3.5 inches to 6 inches, and the diameter is usually from 6 inches to 8 inches greater than the diameter of the commutator, the difference depending upon the possibility of making a good mechanical construction of the end connections. The number of slots in the armature and the number of segments in the commutator must be a multiple of both the number of phases and the number of poles.

Armature Winding. — The winding of the armature is usually of the multiple-drum type, although the series winding may be used. The turns per pair of poles are divided by equally-spaced taps (to the slip rings) into as many groups as there are phases. The number of turns in series between brushes is adjusted for the proper direct e.m.f. and a reasonable value of flux per pole. The alternating e.m.f. bears a definite relation to the direct e.m.f. depending upon the type of connection (*see above*), and also to some extent upon the shape and length of pole arc.

Flux Density in Air Gap. — The air gap or pole-face flux density usually has a value ranging from 40 to 60 kilolines per square inch as in generators.

Damping Copper in Pole Face. — In the pole face of every converter a squirrel-cage winding should be provided to assist in starting and to prevent hunting. The total cross-section of copper per pole ranges approximately

from 1/10 to 1/5 of the armature copper per pole and the end rings must be of reasonable cross-section compared to the bars. The joints between bars and end rings must be carefully made.

Shunt and Series Fields. — The determination of the length of armature, length of commutator and the design of the field follow the same laws as the design of these parts for a d-c. generator. The proportioning of the series field results from the considerations given above under *Field Excitation*, the problem being that a certain amount of leading current is required at a given load and to make the armature take this leading current the field excitation must be increased by a certain number of ampere turns, from which the number of turns in the series field can be determined.

Equalizer Connection. — In large multi-polar machines it is customary to connect to a common ring all commutator bars which are at the same potential; these "equalizer connections" avoid local cross-currents in the armature from flowing through the brushes and causing bad commutation. These cross-currents are caused by unequal or uneven air gap.

Shaft, Bearings, Etc. — Since the transfer of energy is in the conductors themselves, there is no mechanical torque other than that to overcome friction and core-loss. Therefore the shaft, bearings and mechanical housing of a rotary converter are quite light and present no particular mechanical difficulties in mechanical design. For the same reason converters do not require very elaborate foundations. Machines of less than 1000 kilowatt capacity are usually supplied with a base and are complete in one piece, while larger sizes are supplied with foundation plates.

Kw. rating	500	300
Frequency	25	60
Core-loss	1.00	1.75
Armature RI^2	0.55	0.60
Shunt field RI^2	0.70	0.60
Brush RI^2	0.40	0.40
Bearing friction	0.55	1.50
Brush friction	0.30	0.65
Efficiency	96.50	94.50

Efficiency and Losses. — The efficiency and distribution of losses of a typical 25-cycle and 60-cycle converter are shown in the accompanying table. All values are in per cent of input at full load.

EXAMPLES OF DESIGN. — In the following table are given design data on four representative converters of different capacities.

TESTING OF CONVERTERS. — The following are the usual tests made on converters to determine the efficiency, regulation, heating and to show any defects in construction.

1. Resistance of Armature, Shunt Field and Series Field. — The armature resistance is usually measured between points on the commutator diametrically opposite and the equivalent resistance calculated from this value by the equation

$$\text{Equiv. Res.} = \frac{4 \times (\text{diametrical resistance})}{(\text{number of poles})^2}.$$

SYNCHRONOUS CONVERTERS

Armature diameter	inches	25.6	36	21	28
Slots per pole		24	24	6 5/6	21
Armature length	inches	11	17.25	7.1	10.5
Commutator diameter	inches	19.7	28	16.5	20
Number of segments		288	288	194	252
Periph. speed of commutator	feet per minute	3800	3650	4300	6280
Volts per bar	volts	8.3	12.5	13.6	14.3
Pitch segments	inches	0.17	0.306	0.266	0.25
Armature diameter per pole	inches	6.4	6	3.5	4.75
Nominal U†	amperes	6000	3600	2630	3400

* σ = ampere conductors (d-c.) per inch periphery.

† U = amperes (d-c.) per square inch.

To obtain the true RI^2 in a converter armature this equivalent resistance is multiplied by the square of the external direct current and by a constant as given in the accompanying table:

	Theoretical	Commercial
Single phase	1.39	1.47
Three phase	0.56	0.59
Quarter phase	0.37	0.39
Six phase	0.26	0.27

These values only hold if the converter is operating at unity power factor. For any other power factor the reactive component of the alternating current per phase must be found and the square of this component times the resistance per phase of the armature gives the additional RI^2 loss due to the lesser power factor.

2. **No-load Saturation Curve.** — The no-load saturation curve, as in a-c. generators and d-c. generators (q.v.) is usually plotted between commutator voltage and ampere turns of shunt field.

3. **Core-loss** as in a-c. and d-c. generators (q.v.).

4. **Phase Characteristic** at no load and at full load as in synchronous motors (q.v.).

5. **Synchronous Impedance** as in a-c. generators (q.v.).

6. **Starting Tests** to determine current and voltage necessary to start the converter on a-c., time to reach full speed, and voltage induced in field windings as in synchronous motors (q.v.).

7. **Heat Run.** — This may be made either with a resistance for load or two similar converters may be tested in parallel by the Hopkinson or "pump back" method; see *Transformers*. In addition to a source of d-c. power of the rated voltage of the converter to supply the losses, either a d-c. booster or an a-c. potential regulator is needed to adjust the load.

8. **Insulation Tests.** — See *Generators, Alternating-current*, and *Standardization Rules of the A.I.E.E.*

9. **Pulsation Test.** — A synchronous converter is very sensitive to any change in impressed voltage or frequency. A sudden change in either of these factors will cause a pulsation which will start the machine hunting, as discussed in the article on *Motors, Synchronous*. This hunting may increase until the machine falls out of step or flashes over. To determine whether a converter has a dangerous tendency of this kind, a test is made in which two similar machines are supplied with power from a common generator. Between each converter and the common connection a resistance is placed in each a-c. line, having a value that will give with full-load current a drop in voltage of 15 per cent of the rated voltage of the machine. Thus there is 15 per cent *RI* drop between each converter and the generator and 30 per cent between the two converters. The two machines are operated at no load and at rated voltage with the shunt fields adjusted for minimum input. The voltage across the commutators is observed for any periodic variation. Then the field of one machine at a time is varied from half normal to twice the normal value and any indications of periodic variations of the direct voltage noted. If the machines have a proper damper winding in the pole faces, they should not develop any dangerous hunting, even under the above unfavorable conditions.

SPECIFICATIONS FOR SYNCHRONOUS CONVERTER.* — The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

Principal Characteristics and Conditions of Service. — Use to which converter is to be put, such as railway, lighting, motor driving or battery charging. Whether it is to convert from a-c. to d-c. or vice versa. Voltages and number of phases. Nominal rating in kilowatts or Institute rating in kilowatts. Frequency and speed.

Style and Description; Details of Construction. — Whether interpole; whether shunt or compound wound, or whether there is a split-pole field winding; whether rheostat is to be supplied for shunt field; if so, its characteristics. Proposed method of starting and whether starting apparatus is to be supplied. Whether a speed-limit device is required; if so, the shunt field rheostat shall have sufficient resistance to speed the machine for testing the speed-limit device, the latter being set at 15 per cent over rated speed. Whether an end play device (or oscillator) is desired and if so, what type or types are acceptable.

Work to be Done by Other Contractors. — Whether the synchronous converter contractor is to furnish and install the following: Main wiring, field wiring, field-rheostat grids, dial plate and chains, starting panels, starting rheostat or motor generator, foundations.

Performance and Tests. — Temperature rises upon which nominal and Institute ratings are to be based. Overload capacity (*see Standardization Rules of the A.I.E.E.*). Commutation limits. Efficiency at 25, 50, 75, 100, 125 and 150 per cent nominal load. High-potential tests of insulation. Requirements regarding effect of moisture upon insulation. Converters shall operate in parallel without "hunting" from no load to stated (say 200 per cent) overload, provided drop in high-tension lines due to resistance between any converter and

* By W. A. Del Mar.

any other synchronous apparatus in the system does not exceed a stated value (say 20 per cent), and provided that the phase variation does not exceed a stated value (say 2.5°). What voltage regulation is required, how it is to be obtained and whether it is to be hand or automatic. If the converter is shunt wound, state voltage-regulation requirements. What per cent reactance between a-c. bus and converter is required?

OPERATION OF CONVERTERS. — In the operation of synchronous converters the points mentioned below should receive special attention.

Transformer Connections. — The usual methods of connecting transformers to supply converters are shown diagrammatically in Figs. 1 to 6 and are discussed above in the section on *Voltage Ratios* and also in the article on *Transformer Connections*. Of the three-phase to six-phase connections the choice must be made with some care, as all connections are not equally good for each specific use of the converter.

Methods of Starting. — The several methods of starting converters are as follows:

Alternating-current Starting which is the same as the starting of motors; see *Motors, Synchronous*.

Direct-current Starting. — The machine is started as a direct-current shunt motor and synchronized on the a-c. side after it is up to speed. This requires less power, but takes more time and more skill in order to synchronize.

Starting with Auxiliary Motor. — This involves the extra cost and extra continuous loss of the auxiliary induction motor. It is no more efficient than starting by direct current and requires the same amount of time.

Combination Alternating- and Direct-current Starting. — The machine is started up with direct current, then disconnected from the d-c. mains and connected to a low-voltage tap of the a-c. supply and brought up to full speed. This method is more economical of power and time but requires more starting apparatus than either the a-c. or d-c. methods.

Field Break-up Switch. — All converters are supplied with a switch to open the field in several places to avoid the strain of the high potential induced in the field during starting and to reverse the direction of current in the field after the machine is up to speed in order to reverse the polarity in case it should not be right. This is usually a double-throw switch with several poles.

End-play Device. — In order to prevent the brushes from wearing grooves in the commutator and collector rings a device is mounted upon one end of the shaft to move the shaft end-wise back and forth periodically. In small machines this is a mechanical device consisting of a ball running between two warped surfaces. In large machines it consists of an electromagnet which periodically pulls out the armature a short distance. The magnetic pull of the main field poles pulls the armature back.

Speed-limiting Device. — In case a converter should be disconnected from the main a-c. generating circuit and still remain connected so that it would tend to operate from the d-c. side there is danger of its speed becoming dangerously high. To avoid this a centrifugal governor is placed on the shaft and arranged to electrically operate the main d-c. switches of the converter.

VOLTAGE REGULATION. — There are several methods of regulating the voltage delivered by the commutator of a converter.

Compound-wound Converter with External Reactance. — This method is automatic and will give about 10 per cent variation in voltage. It is standard

Regulating or Split-pole Converter. — With this type of converter the voltage regulation is gradual and normally accomplished by hand, but by the addition of an automatic voltage regulator may be made automatic.

Shunt-wound Converter with Induction Regulator. — A large variation in voltage is possible but this method does not respond to quick changes. It is quite generally used in lighting work.

Shunt-wound Converter with Synchronous Booster. — A synchronous generator is carried on the same shaft as the converter and connected in series between the transformers and the collector rings of the converter. The method is good but expensive.

Shunt-wound Converter and Taps on the Transformers. — The voltage ratio of the transformers may be varied. This is usually accomplished by connecting the line to different taps on the primaries, which involves opening the circuit or short-circuiting a portion of the transformer at each change.

WEIGHTS, SPEEDS AND COSTS. — The weights, speeds, over-all dimensions and approximate costs of two commercial lines of converters are given in the following table. The first group is a line of 25-cycle converters and the second a line of 60-cycle converters for railway work. It will be noted that smaller capacities are three-phase machines, whereas the larger capacities are six-phase machines. The six-phase connection makes possible a saving in material at the expense of an increase in manufacturing labor.

The costs given are only approximate, as such figures vary enormously with commercial conditions. There is a tendency at present to reduce both the weight and cost of these machines. All these machines are designed to give their rated output continuously with a rise of 35° C. and an overload of 50 per cent for two hours with a rise of 55° C.

WEIGHTS, SPEEDS AND COSTS

Poles	Kw.	R.p.m.	Volts	Phases	Over-all dimensions			Wt., lb.	Cost per kw. dollars
					Leng., in.	Width in.	Ht., in.

[W. I. SLICHTER.]

CONVEYORS. — (*See also Power Stations; Telpherage.*) A conveyor is a mechanical device for the continuous handling of materials along a horizontal or inclined plane. There are four general types of conveyors, viz., the scraper or flight, the screw, the bucket and the belt.

THE FLIGHT CONVEYOR consists of a trough of any desired cross section through which are pulled a series of scrapers or "flights" attached to an endless chain. The improved forms of this type of conveyor have sliding shoes or rollers attached to the flights or to the chains, supported on runways.

Capacity. — The following table by S. B. Peck (*Trans. A.S.M.E., 1910*) gives the capacities of flight conveyors in tons of coal per hour when the conveyor is operated at a speed of 100 feet per minute.

CAPACITY OF FLIGHT CONVEYORS

Size of flight, in.	Horizontal				Inclined		
	Flights spaced			Lb. per flight	10°	20°	30°
	18 in.	18 in.	24 in.		24 in.	24 in.	24 in.
	Tons	Tons	Tons		Tons	Tons	Tons
4 by 10	33.75	30	22.5	15	18	14.25	10.5
4 " 12	42.75	38	28.5	19	24.5	18	13.5
5 " 12	51.75	46	34.5	23	28.5	22.5	16.5
5 " 15	69.75	62	46.5	31	40.5	31.5	22.5
6 " 18	.....	80	60	40	49	40.5	31.5
8 " 18	.....	120	90	60	72	57	48
8 " 20	.....	...	105	70	84	66.5	56
8 " 24	.....	...	135	90	120	96	72
10 " 24	.....	...	172.5	115	150	120	90
10 " 30	.....	...	220	147	184	146	116
10 " 36	.....	...	268	179	225	177	142
10 " 42	.....	...	315	210	264	210	167

Power Required. — The following formula gives approximately the horse power at the head wheel required to operate flight conveyors:

$$H.P. = (ATL + BWS) \div 1000.$$

T = tons of coal per hour; L = length of conveyor in feet, center to center; W = weight of chain, flights and shoes (both runs) in pounds; S = speed in feet per minute; A and B constants depending on angle of incline from horizontal and have the following values.

Angle, deg.	*A*	*B*	Angle, deg.	*A*	*B*	Angle, deg.	*A*	*B*
0	0.343	0.01	10	0.50	0.01	30	0.79	0.009
2	0.378	0.01	14	0.57	0.01	34	0.84	0.008
4	0.40	0.01	18	0.63	0.009	38	0.88	0.008
6	0.44	0.01	22	0.69	0.009	42	0.92	0.007
8	0.47	0.01	26	0.74	0.009	46	0.95	0.007

For suspended flight conveyors take B as 0.8 and for roller flights as 0.6 of the values given in the table.

Screw Conveyors. — Screw conveyors consist of a helical steel flight, either in one piece or in sections, mounted on a pipe or shaft, and running in a steel or wooden trough. These conveyors are made from 4 to 18 inches in diameter, and in sections from 8 to 12 feet long. The speed ranges from 20 to 60 r.p.m. and the capacity from 10 to 30 tons of coal per hour. It is not advisable to use this type of conveyor for coal, except the smaller sizes, as the flights are easily damaged by any foreign substance of unusual size or shape.

BUCKET CONVEYORS are of two types, having rigidly connected and pivoted buckets respectively. The buckets are carried by an endless chain driven by sprockets or pawls. Rigid buckets are used to convey coal and other materials over considerable distances when there is no intermediate point of discharge. They are built to carry as much as 2 tons of coal per minute.

Pivoted buckets may be used both as conveyors and elevators, and are particularly well adapted to the handling of coal and ashes in power plants. Their advantages are slow speed, silent operation, adaptability to change of direction without transfer, high efficiency and easy renewal of worn parts. Their disadvantages are danger of buckets sticking or upsetting and jamming in the supports, and the difficulty of preventing spill at the loading and turning points. Spilling in loading may be prevented by the use of special loading devices, by providing overlapping lips on the buckets or by placing small buckets between the main buckets to catch the spill.

Capacity. — Buckets are usually of 2-feet pitch, and range in width from 18 to 48 inches. They run at low speeds, usually not over 50 feet per minute, 40 feet per minute being the usual speed. At the latter speed the capacities when handling coal vary from 40 tons per hour for the 18-inch width to 120 tons per hour for the 48-inch width.

Power Required. — Prof. E. F. Miller gives the following formula for calculating the power required for a bucket conveyor making a rectangular circuit:

$$P = 0.004\,CL,$$

where P is the horse-power required, C is the capacity of the conveyor in tons of coal per hour, and L is the total lift in feet. This is an empirical formula deduced from numerous data on coal conveyors having capacities of from 20 to 50 tons and operating at speeds of from 40 to 55 feet per minute, and making lifts of from 40 to 80 feet. The power given by the above formula is for the conveyor loaded to its full capacity. The conveyor when running empty will require from 40 to 60 per cent of this. The smaller the conveyor the larger the percentage of power empty to power loaded.

BELT CONVEYORS. — Rubber and cotton belt conveyors are used for handling coal, ore, sand, gravel, etc., in all sizes. They combine a high carrying capacity with low power consumption. In the majority of cases the belt is troughed by means of idler pulleys set at an angle from the horizontal and placed at intervals along the length of the belt. Belt conveyors may be used for elevating materials up to about 23° incline. The belt may be run at any speed from 200 to 800 feet per minute, and may be from 12 inches to 60 inches in width. The most serious objection to belt conveyors is the lack of durability of the belts, their liability to destruction from accidental causes and the expense of their frequent renewals.

Link belts (*see Chains and Chain Drive*) are also used for conveying purposes.

Capacity. — The following table gives the capacity of the more common sizes of belt conveyors:

CAPACITY OF BELT CONVEYORS IN TONS OF COAL PER HOUR

Width of belt, in.	Velocity, feet per minute			Width of belt, in.	Velocity, feet per minute				
	300	350	400		300	350	400	450	500
12	34	..	...	20	96	112	128	...	...
14	47	..	...	24	139	162	186	210	...
16	62	72	82	30	218	254	290	326	...
18	78	91	104	36	315	368	420	472	520

For materials other than coal, the figures in the above table should be multiplied by the coefficients given in the table below:

Material	Coefficient	Material	Coefficient
Ashes (damp)	0.86	Earth	1.4
Cement	1.76	Sand	1.8
Clay	1.26	Stone (crushed)	2.0
Coke	0.60		

Power Required to drive a belt conveyor (*C. K. Baldwin, Trans. A.S.M.E., 1908*) depends on a great variety of conditions, as the spacing of idlers, type of drive, thickness of belt, etc. In figuring the power required, the belt should run no faster than is necessary to carry the desired load. If it should be necessary to increase the speed, the load should be increased in proportion and the power figured accordingly.

For level conveyors the horse-power required is

$$P = C \times T \times L \div 1000.$$

For inclined conveyors

$$P = (C \times T \times L \div 1000) + (T \times H \div 1000).$$

C = power constant from table below; T = load, tons per hour; L = length of conveyor, center to center, feet; H = vertical height material is lifted, feet; S = belt speed, feet per minute; B = width of belt, inches.

For each movable or fixed tripper add horse-power in column 3 of table. Add 20 per cent to horse-power for each conveyor under 50 feet long. Add 10 per cent to horse-power for each conveyor between 50 and 100 feet long. The formulas above do not include gear friction, should the conveyor be gear-driven.

	1	2	3	4	5
Width of belt, Inches	*C* for material weighing from 25 lb. to 75 lb. per cu. ft.	*C* for material weighing from 75 lb. to 125 lb. per cu. ft.	H.P. required for each movable or fixed tripper	Minimum plies of belt	Maximum plies of belt

COOLING SYSTEMS FOR POWER STATIONS. — When the supply of cooling water is limited or expensive, economy requires that it shall be artificially cooled and used continuously. This cooling is accomplished by natural or forced evaporation in open ponds, spray fountains, a series of artificial cascades or in cooling towers. The latter device is largely used.

COOLING TOWERS. — Cooling towers are usually made in the shape of large cylinders of sheet steel, filled with narrow boards or laths arranged in geometrical forms, or hollow tile, or wire network, so arranged that while the water, which is sprayed over them at the top, trickles down through the spaces it is met by an ascending air column. The air is furnished either by disk fans at the bottom or is drawn in by natural draft. In the latter case the tower is made very high, say 60 to 100 feet, so as to act like a chimney.

Make-up Water. — When used with jet condensers, the water produced by the condensation of the exhaust steam is sufficient to make up for the evaporation in the tower, and therefore only enough water for the boiler feed need be supplied continuously. In fact, the condensed steam is, as a rule, more than sufficient to make up for the loss due to evaporation, and there results a slight overflow, which carries with it the oil from the engine cylinders and tends to clean the system of the oil that would otherwise accumulate in the hot-well.

When a cooling tower is used with a surface condenser make-up water must be added to the cooling water, the amount ranging from 3 to 4 per cent, but in this case the boiler feed water can be used over and over again with but slight loss, provided the oil (there is none with turbines) is eliminated by suitable separators.

Reduction in Temperature Obtainable. — With a properly designed cooling tower the temperature of the hot water (and condensed steam in the case of a jet condenser) can be reduced 40 to 50° F.

Power Required for Forced Draft in Tower. — The power required for the fan, when forced draft is used, averages 2 per cent of that developed by the main engines during the summer months, when maximum volume of air is required, and about 1 per cent during the winter months.

COSTS. — Cooling-tower costs vary greatly with climatic and operating conditions. When these are relatively favorable the cost may be kept as low as $2.50 per kilowatt for natural draft towers and $3.60 for fan draft. Under ordinary central-station conditions the costs will probably average $3.50 and $5.00 per kilowatt respectively for the two types of towers.

BIBLIOGRAPHY. — Additional data on cooling towers, ponds and spray fountains and numerous references to original papers will be found in Gebhardt's *Steam Power Plant Engineering*. See also Kent's *Mechanical Engineers' Pocket-Book*.

[WM. KENT.]

COPPER. — (*See also Electrochemical Processes, Industrial; Wires and Cables, Bare.*) The following discussion applies primarily to copper for electrical conductors.

COMPARISON OF LAKE AND ELECTROLYTIC COPPER. — The copper mined in the vicinity of the Great Lakes is almost pure copper. Copper made from the various ores of the metal must be refined (usually electrolytically) to reduce it to the same degree of purity. Lake copper possesses both high conductivity and excellent mechanical qualities but costs from ⅛ cent to ¾ cent per pound more than electrolytic copper. Why the latter should be inferior to Lake is difficult to explain, but experience shows that the general run of commercial electrolytic copper is by no means uniform in physical qualities and as a general thing is distinctly inferior to Lake for wire-drawing purposes. The lower price of electrolytic copper results in its use by many manufacturers although the wire is generally inferior to a slight extent.

ROLLING-MILL PROCESSES. — The refined copper comes to the rod mill in bars weighing about 200 pounds each. These bars frequently have ridges along the sides, due to faults in castings, and the surface is often covered with a layer of oxide. They are heated in a furnace until sufficiently soft for rolling and are passed through a series of rolls diminishing in size until a rod of the proper diameter is obtained. The rod is then coiled up and immersed in a pickling liquid (10 per cent H_2SO_4) in order to dissolve the oxide formed during rolling. It is then washed and dipped in a fluid tallow mixture.

WIRE-MILL PROCESSES. — The rods having cooled are connected together by brazing and are drawn through a series of dies of decreasing diameter. The dies give the wire a dense hard exterior coating which increases its tenacity. As the strength obtainable is almost a direct factor of the work expended upon the wire, the smaller the size the greater the tensile strength per square inch, so that the strength of the wire is readily varied by changing the size of the rod and the number of dies.

Defects in Wire. — One of the most serious defects occurring to wire at this point is from ridged bars as above described. Ordinarily the bar will not be sufficiently heated to dissolve the copper oxide on the surface so that as the softened bar enters the first passes of the rolls, the ridges are lapped over, inclosing the oxide scale. The subsequent passes and the drawing through the dies obscure this flaw almost entirely, but it remains a serious menace to the toughness and the resistance to wear of the copper.

A second cause of trouble arises at the same point by overheating the copper in the softening furnace, in which case copper oxide is formed on the surface and quickly dissolves through the entire bar, thereby increasing the oxide content and tending toward the production of brittleness. Both of these dangers can be avoided by careful selection of the bars and by proper regulating of the temperature of the softening furnace.

As the production of the hard surface from drawing is at best a rather delicate operation, careless handling, uneven welding of the rods and unequal temperature of the wire while passing through the dies will all produce noticeable effects in the quality of the finished wire, so that care throughout the mill is absolutely necessary for the best results.

It, therefore, appears that the most efficient wire must possess not only high conductivity but the maximum torsion and tensile strength possible in commercial copper and that to obtain this it is first necessary to use high-grade copper and to prevent an excess of cuprous oxide entering it at any stage of the manufacture, and, secondly, to select as perfect bars as possible and to observe extreme

care in every treatment through which they pass. (*Adapted from article by Carl F. Woods, Electric Railway Journal, 1909, Vol. 33, p. 195.*)

ANNEALING. — All wire when first drawn is more or less hard. It may be softened by annealing, i.e., by heating to a high temperature and cooling slowly.

MECHANICAL PROPERTIES. — (*See Wires and Cables, Bare, for tables of tensile strength, etc., of various sizes of wire.*) The more important mechanical properties of copper are discussed in some detail below.

Tensile Strength and Elongation of Soft Annealed Copper. — The tensile strength of soft annealed copper is about 30,000 to 33,000 pounds per square inch with an elongation of about 25 per cent (in 10 inches) at the fracture. It has no true elastic limit, permanent elongation being produced by very small loads.

Tensile Strength and Elongation of Hard-drawn Copper. — (*See Wires and Cables, Bare, for tensile strength of various sizes of wire.*) According to D. R. Pye, hard-drawn copper in wires up to ½ inch diameter varies in tensile strength with the diameter according to a linear law of the form

$$T = 70{,}000 - 45{,}000\,D,$$

where T = tensile strength, pounds per square inch, and D = diameter of wire, inches.

The above constants agree approximately with the tables of the American Society for Testing Materials and represent values somewhat under those usually obtained.

The elongation at fracture is approximately represented by

$$E = 4\sqrt{D},$$

where E = per cent elongation at fracture.

Tests by G. C. Batson on 50-foot lengths of hard-drawn copper showed a tensile strength only ½ per cent less than that of 10-foot lengths, a fact which indicates that the material is very uniform.

Modulus of Elasticity of Hard-drawn Copper. — The modulus of elasticity of hard-drawn copper varies from 12×10^6 to 20×10^6, the higher values applying to small wires. The following tests by G. C. Batson are typical of commercial copper.

Diameter, in.	0.158	0.138	0.112	0.094	0.079	0.066	0.049
Modulus, lb. sq. in. units	17.7×10^6	17.9×10^6	17.5×10^6	17.7×10^6	17.1×10^6	19.5×10^6	19.2×10^6

An apparent modulus of 12×10^6 is often obtained from an initial test, due to straightening-out. (*See also Wires and Cables, Bare.*)

Elastic Limit of Hard-drawn Copper. — The true elastic limit of hard-drawn copper, or load at which permanent set begins, is not the same as the point where the strain begins to increase more rapidly than the stress. The latter point is usually between 30,000 and 35,000 pounds per square inch and the former, somewhat below (*see Wires and Cables, Bare*).

Density. — The density of copper or, for all practical purposes, its specific gravity referred to water, is 8.89 at 20° C. This is the value which has been adopted as standard by the American Institute of Electrical Engineers, and most

the Calumet & Hecla Smelting Works, and the Reichsanstalt have indicated this as a mean.

CONDUCTIVITY AND RESISTIVITY. — (*See also Resistance and Conductance; Wires and Cables, Bare.*) F. A. Wolff and J. H. Dellinger give the resistivities of 89 samples of commercial copper from 14 important refiners and wire manufacturers in this and other countries. The mean for annealed wire is: Resistivity in ohms per meter-gram at 20° C. = 0.15292; per cent conductivity = 100.25. (Per cent conductivity is computed on the basis of 100 per cent conductivity corresponding to the standard resistivity of 0.15328 ohm per meter-gram at 20° C.) The mean result of data furnished by a large wire-manufacturing company, representing tests on more than 100,000,000 pounds of copper, is also given; for example, for annealed samples: Resistivity in ohms per meter-gram at 20° C. = 0.15263; per cent conductivity = 100.42.

Conductivity of Hard-drawn Copper. — The conductivity of hard-drawn No. 12 B. & S. wires was found to be less than the conductivity of annealed wires by a mean value of 2.7 per cent. The difference between the conductivity of annealed and hard-drawn wires increases as the diameter of the wire decreases. The lowest resistivity and highest conductivity found for a hard-drawn wire were: Resistivity in ohms per meter-gram at 20° C. = 0.15386; per cent conductivity = 99.62; and for annealed wire were: resistivity in ohms per meter-gram at 20° C. = 0.15045; per cent conductivity = 101.88.

Effect of Bending on Conductivity. — Copper wire apparently decreases in conductivity when bent, but the greater part of this is caused by local changes in cross-section. This effect is negligible unless the wire is bent to a very small radius.

Effect of Melting. — Electrolytic copper which is drawn without having been melted has a higher conductivity than that which has been melted, J. H. Dellinger recording copper thus drawn as having a conductivity as high as 101.71 per cent after annealing at a dull-red heat. Lake copper likewise drawn without having been melted gave conductivities as high as 101.88 after annealing.

Temperature Coefficient of Resistivity. — It has been found by J. H. Dellinger (*Bulletin No. 147, Bureau of Standards, 1910, Vol. 7, No. 1*) that the temperature coefficient of copper is proportional to the conductivity instead of being virtually a constant, as hitherto assumed. This fact may be expressed by saying that the change of resistivity per degree C. of a sample of copper is 0.000597 ohm per meter-gram or 0.00681 micro-ohm per centimeter cube. (Dellinger's original figures were subsequently changed slightly; *see Circ. No. 31 of Bureau of Standards, 1912 ed.*) The 20° C. temperature coefficient of a sample of copper is found by multiplying the per cent conductivity by 0.00393 and dividing by 100. These rules apply only to copper furnished for electrical use and to the temperature range of 10° C. to 100° C. over which the temperature coefficient was found to be linear. The following table gives the temperature coefficients a_T in the formula:

$$R_t = R_T[1 + a_T(t - T)].$$

Ohms per meter-gram at 20° C.	Per cent conductivity	α_0	α_{15}	α_{20}	α_{25}	α_{30}
0.16134	95	0.00403	0.00380	0.00373	0.00367	0.00360
0.15966	96	0.00408	0.00385	0.00377	0.00370	0.00364
0.15802	97	0.00413	0.00389	0.00381	0.00374	0.00367
0.15753	97.3	0.00414	0.00390	0.00382	0.00375	0.00368
0.15640	98	0.00417	0.00393	0.00385	0.00378	0.00371
0.15482	99	0.00422	0.00397	0.00389	0.00382	0.00374
0.15328	**100**	0.00427	0.00401	**0.00393**	0.00385	0.00378
0.15176	101	0.00431	0.00405	0.00397	0.00389	0.00382

The boldface values in the table have been adopted as standard by the American Institute of Electrical Engineers (*see Standardization Rules*).

[W. A. Del Mar.]

CORONA, ELECTRIC. — (*See also Electron Theory; Spark Gap; Transmission Lines.*) When the difference of potential between two conductors which are insulated from each other by air is increased from a low to successively higher values, the following sequence of phenomena is observed, provided the conductors are relatively far apart compared with their dimensions: 1. When the potential is but a few volts only an extremely small (practically negligible) current passes between the two conductors, i.e., the insulation resistance is very high. 2. As the potential is increased, the insulation resistance remains practically constant until a certain value of the voltage is reached (depending upon the dimensions, distance apart of the conductors, etc.); when the insulation resistance falls to a much lower value, a bluish light appears around at least those parts of the conductors which are closest together, and a hissing noise is produced; these effects all start at the same value of the voltage. The bluish light is called the "corona" and the accompanying phenomena are called "corona effects." 3. As the voltage is still further increased the sheaths of light extend a greater distance from the conductors until finally a spark passes between them.

If the conductors are near together compared with their dimensions the spark passes without being preceded by the bluish light, i.e., no corona appears.

The appearance of the discharge at the positive conductor is different from the appearance at the negative conductor. If instead of a constant potential difference an alternating one is used the phenomena noticed are very much the same except that now the discharge is not continuous but appears and disappears with a frequency twice that of the potential difference.

CORONA ON TRANSMISSION LINES. — The loss of power accompanying the appearance of the corona on high-tension transmission lines is an appreciable one; in fact, in the present state of the art, the corona loss is the chief obstacle to the use of voltages above 150,000. The most comprehensive study of the "laws" of the corona thus far made is that by F. W. Peek, Jr. (*Trans. A.I.E.E., 1911, Vol. 30, p. 1889; Proc. A.I.E.E., June, 1912*). Peek's investigations were made with alternating voltages on an outdoor transmission line about 500 feet long, under all the variable conditions of spacing, size of conductor, storms, etc., usually met with in practice, these tests being supplemented by extensive laboratory investigations. Peek's results are summarized in the following paragraphs.

Disruptive Potential Gradient. — In his formulas Peek uses a factor which he calls the "disruptive" critical potential gradient. This "disruptive" gradient is not the potential gradient corresponding to the actual formation of the corona on the wires of a transmission line, but is the potential gradient corresponding to the break-down voltage of an air gap of 0.5 cm. or more in length between conductors of very large radius of curvature, i.e., practically plane surfaces (*see article on Spark Gap*). Peek obtains its value by extrapolating his experimentally determined curves, and thus obtains 75.7 kilovolts per inch (29.8 kilovolts per centimeter) maximum, which is equivalent to 53.5 kilovolts per inch effective value for a sine-wave voltage. This value is in close agreement with the values obtained directly for the potential gradient required to break down a spark gap between conductors of large radius of curvature when the gap is greater than 0.5 cm. in length.

The following formulas apply to either a single-phase or symmetrically arranged three-phase line. Sine-wave voltage is assumed and all voltage values are effective or r.m.s. values. Let

a = radius of each conductor in inches.
D = distance, in inches, between centers of conductors.

$H_0 = 75.7 =$ "disruptive" critical potential gradient of air, kilovolts per inch, at 77° F. (25° C.) and 29.92 inches (76 cm.) barometric pressure.

$V_0 =$ kilovolts to neutral corresponding to the potential gradient H_0 at the surface of the wire, assuming a clean, polished cylindrical (circular) surface.

$V_v =$ kilovolts to neutral required to start the corona, called by Peek the "visual" critical voltage.

When the return conductor is so remote that the charge on it produces no appreciable field at the conductor in question *

$$V_0 = 123\, a \log_{10} \frac{D}{a}. \qquad (1)$$

TABLE I. VALUES OF V_0 FOR STANDARD STRANDS †

Effective kilovolts to neutral

Size of wire, cir. mils or A.W.G.	Diam., inches $= 2a$	Feet between wires, center to center $\left(= \frac{D}{12}\right)$							
		3	4	6	8	10	12	15	20
1,000,000	1.152	127.5	136.1	148.9	157.8	164.7	170.3	177.2	186.1
750,000	0.998	114.3	122.0	132.8	140.5	146.4	151.3	157.3	165.3
500,000	0.814	97.7	103.9	112.8	119.0	123.9	127.9	133.2	139.0
350,000	0.681	85.0	90.2	97.6	102.8	107.4	110.2	114.3	119.5
250,000	0.575	74.4	78.8	85.0	89.4	92.9	95.7	99.1	103.5
0000	0.528	69.5	73.5	79.3	83.3	86.5	89.1	92.2	96.3
000	0.470	63.3	66.9	72.0	75.6	78.5	80.7	83.5	87.2
00	0.418	57.6	60.8	65.4	68.6	71.1	73.1	75.6	78.8
0	0.373	52.5	55.4	59.5	62.4	64.6	66.4	68.6	71.5
1	0.332	47.8	50.4	53.9	56.5	58.5	60.1	62.1	64.7
2	0.292	43.1	45.3	48.5	50.7	52.5	53.9	55.6	57.9
4	0.232	35.6	37.4	39.9	41.7	43.1	44.3	45.6	47.4
6	0.184	29.4	30.8	32.8	34.2	35.3	36.2	37.3	38.7

* The potential gradient H, in abvolts per cm., at a point a distance x cm. from the center of a cylindrical wire, due to a charge of Q abcoulombs per cm. on that wire is $2\,Q/x$; the capacity to neutral is

$$C = \frac{1}{2 \log_e \frac{D}{a}} \quad \text{abfarads}$$

and since $Q = CV$, where V is in abvolts, therefore

$$H = \frac{V}{x \log_e \frac{D}{a}} \quad \text{abvolts per cm.}$$

At the surface, $x = a$ and $H =$ the value of H_0 in abvolts per cm., whence the above formula in practical units.

† This table is calculated from the formula $V_0 = 123\, a \log_{10} \frac{D}{a}$ taking for a one-half the over-all diameter of the strand. The values of V_0 given in the table are therefore actually those corresponding to a solid wire of this same diameter; the effect of strand-ing is taken into account by the factor m_0 in Table II.

Visual Critical Voltage in Fair Weather. — Peek's experiments show that the actual voltage, kilovolts to neutral, at which the corona forms* in fair weather may be represented by the formula

$$V_v = m_v \delta \left(1 + \frac{0.189}{\sqrt{a\delta}} \right) V_0, \qquad (2)$$

where m_v ($= 1$ for clean, polished, solid wires) is a factor which takes into account the condition of the surface of the conductors, see Table II, and δ is the specific gravity of the air, referred to air at 77° F. (25° C.) and 29.92 inches (76 cm.) barometric pressure ($\delta = 1$ for these standard conditions). The specific gravity δ is calculated from the formula

$$\delta = \frac{17.95\, B}{460 + t}, \qquad (3)$$

where B = actual barometric pressure in inches, and t = actual temperature in °F.

TABLE II. VALUES OF m_v AND m_0

Surface, etc.	Value of m_v	Value of m_0
Clean, polished wires, solid	1.00	1.00
Weathered or roughened wires, solid	0.93 to 0.98	0.93 to 0.98
7-strand bare cables, decided corona all along conductor	0.82	0.83 to 0.87
7-strand bare cables, local corona all along conductor	0.72	....

Visual Critical Voltage in Foul Weather. — Peek's experiments show that when the wires are thoroughly wet, e.g., in a heavy fog or rain, the visual critical voltage is, to a fair degree of approximation,

$$V'_v = 0.3 \left(1 + \frac{0.512}{\sqrt{a}} \right) V_0. \qquad (4)$$

Smoke, falling sleet, or sleet on the wires also lowers the critical voltage.

Power Loss in Fair Weather. — Peek's experiments show that the power loss in fair weather *in kilowatts per mile of each wire*, when the corona actually appears, may be represented by the formula

$$P = \frac{0.00553}{\delta} f \sqrt{\frac{a}{D}} (V - m_0 \delta V_0)^2, \qquad (5)$$

where

δ = specific gravity of air referred to air at 77° F. (25° C.) and 29.92 inches (76 cm.) barometric pressure, see equation (3). Under standard conditions of pressure and temperature $\delta = 1$.

f = frequency of the impressed voltage.

a = radius of conductor, in inches.

D = distance between conductors, center to center, in inches.

V = actual kilovolts to *neutral*, effective value.

$V_0 = 123\, a \log_{10} \frac{D}{a}$; see Table I.

m_0 = factor depending on the surface of the conductors, see Table II. For clean, polished, solid wires $m_0 = 1$.

* For wires less than 15 diameters apart Peek found that as the voltage was raised a spark passed without being preceded by the corona.

For V less than the visual critical voltage V_v, but greater than $m_0\delta V_0$, the above formula gives a loss which in general is greater than the observed loss. It is probable that were the conductors perfectly clean and their surfaces absolutely uniform, there would be no loss whatever for V less than V_v. The loss that is observed is due to local coronas which form at a lower voltage wherever there is a spot of grease, dirt or other irregularity.

Power Loss in Foul Weather. — The presence of fog or smoke, sleet on the wires or falling sleet, or rain or snow increases the loss. The effect of snow is greater than that of any other weather condition. According to Peek the loss during foul weather may be calculated, to a rough approximation, by using the fair-weather formula taking for m_0 80 per cent of the values given in Table II.

Effect of Humidity, Winds, Frequency, etc. — According to Peek high voltages do not entirely eliminate sleet. Humidity and "vapor products" have no effect on either the critical voltage or on the loss. High winds have no effect upon the loss or critical voltage at ordinary frequencies. The effect of frequency on the visual critical voltage is negligibly small for frequencies between 25 and 60 cycles per second. It should also be noted that the formula for power loss, given above, in which the loss is given as proportional to the frequency, has been tested only for frequencies within the commercial range. It is probable that at extremely low frequencies, the loss decreases less than proportional to the frequency, and approaches a small finite limiting value at continuous impressed voltage.

Ionization of the Air around Charged Wires. — When the corona appears, the air in the neighborhood of the conductors is found to have a conductivity many times larger than its normal value. This conductivity remains for an appreciable length of time after the potential has been cut off. The air is said to be ionized, since, on the assumptions of the electron theory (q.v.), it contains under these conditions a very large number of ions. Whitehead has investigated the relation between the conductivity of the air near the conductors and the voltage between them, and finds that the voltage at which the corona appears is exactly equal to that at which ionization begins. It is now well established that visual corona, power loss and ionization are entirely contemporaneous.

[W. S. GORTON.]

COUPLINGS, DIRECT.—(*See also Belts and Belting.*) Couplings for connecting electrical apparatus together or to other machines can be divided into two distinct classes, namely, solid and flexible.

SOLID COUPLINGS (Fig. 1) are usually of the flanged type and consist of two steel castings rigidly bolted together. This type should be used where the two machines are mounted on a common iron base and where an exact alignment is possible. Large flanges should be provided for overcoming bending stresses which may occur when the couplings carry part of the load such as, for example, in three bearing sets. See also article on *Machine Tools, Electrical Operation of.*

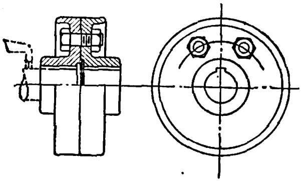

Fig. 1. Solid Flange Coupling

FLEXIBLE COUPLINGS are mainly used to connect machines which cannot be lined up properly or where there is fear that alignment cannot be maintained. Many different kinds of flexible couplings are in use, and they may be divided in two general classes, insulated and uninsulated. The insulated couplings are composed of castings separated by leather or rubber, as a flexible and insulating medium. The principal types of flexible couplings in use are the leather link, the laced belt, the rubber buffer and the mill-type coupling.

Leather-link Flexible Couplings (Fig. 2) consist of two iron castings connected together through leather punchings fastened at the ends by bolts to the alternate halves. For the smaller sizes these links are usually replaced by a single leather disk which connects both halves by means of bolts alternately fastened through opposite halves. The torque stresses are transmitted through these links or disks to the bolts which fasten them to the castings.

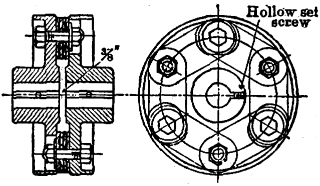

Fig. 2. Leather-link Flexible Coupling

In order to allow sufficient play for the heads of the bolts, alternate holes are bored to a large diameter, the bolts accurately fitting the other holes in the castings. By this means flexibility is obtained and a small amount of end or side play is permissible between the shafts of the two machines to which each half coupling is securely keyed. This type of coupling is recommended for shafts up to 3½ inches in diameter. For shafts between 3½ inches and 5 inches in diameter either this type or the leather-laced type may be used.

Leather-laced Flexible Couplings (Fig. 3) are recommended for shafts above 3½ inches in diameter on account of their structural advantages. They consist of two steel rings, an outer and an inner, with cast-iron hubs bolted to them. Slots are formed in these rings through which an endless leather belt is interwoven.

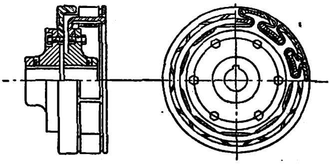

Fig. 3. Leather-laced Flexible Coupling

This construction not only gives great flexibility but, due to the two rings being concentric, it is not subjected to bending strains and therefore is espe-

cially adapted for transmitting a high torque commensurate with the strength of the belt and the size of the coupling employed.

As the outer ring of the coupling is only connected to the shaft of the machine through the coupling hub which is keyed to the shaft, machines using this form of coupling can be readily disconnected without unlacing or interfering with the coupling belt. To do this it is only necessary to remove the bolts, holding the outer ring to the hub. This partial disassembling also aids in the replacing of a worn-out belt without removing the coupling from the machine.

Rubber-buffer Flexible Coupling. — This coupling is made up of two cast-iron spiders, the small interlocking arms of which are separated by cylinders of soft rubber. The rubber cylinders are held in place by projecting plates screwed to the arms of one of the spiders. The construction of this type of coupling affords great flexibility as well as insulating qualities. This type of coupling was once much used on account of its high-insulating qualities but is now to a great extent being superseded by the two previous types.

Mill-type Flexible Coupling (Fig. 4). — Where the conditions are too severe for the belt or rubber of the flexible couplings described above, that is, where there is much grit or hot vapor present and where noise is not objectionable, the mill-type flexible coupling shown in Fig. 4 should be used. This is a rough sturdy coupling consisting of three steel castings, two of which are identical and called the "pods," while the center is called the "box." The most extensive use for this coupling has been in steel mills. Best results are obtained from this coupling when it is used on a constant load, as the noise under these conditions is at a minimum.

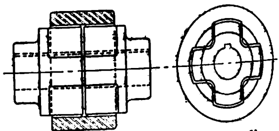

Fig. 4. Mill-type Flexible Coupling

PROPER SIZE OF COUPLING. — The selection of the proper coupling should be determined by calculation and not by the method of choosing the bore corresponding to the shaft diameter. The coupling should have sufficient capacity to take care of the overload capacity of the motor or generator, as the case may be.

[D. B. RUSHMORE, assisted by E. A. LOF.]

CRANES. — (*See also Blocks and Tackle; Controllers; Hoists, Electric; Telpherage.*) A hoist is a machine for raising and lowering weights. A crane is a hoist with the added capacity of moving the load in a horizontal or lateral direction. That part of a crane carrying the hoist and movable with respect to the main structure of the crane is called the "trolley." Cranes are divided into two classes as to their motions, viz., rotary and rectilinear.

Rotary Cranes may be classified as follows:

Swing-cranes. — Having rotation, but no trolley motion.

Jib-cranes. — Having rotation, and a trolley traveling on the jib. When the jib or boom is movable, carrying a sheave on the end, the device is called a *derrick.*

Column-cranes. — Identical with the jib-cranes, but rotating around a fixed column (which usually supports a floor above).

Pillar-cranes. — Having rotation only; the pillar or column being supported entirely from the foundation.

Pillar Jib-cranes. — Identical with the last, except in having a jib and trolley motion.

Derrick-cranes. — Identical with jib-cranes, except that the head of the mast is held in position by guy-rods, instead of by attachment to a roof or ceiling.

Rotary cranes arranged so that they may be readily moved from place to place may be classified as:

Walking-cranes. — Consisting of a pillar or jib-crane mounted on wheels and arranged to travel longitudinally upon one or more rails.

Locomotive-cranes. — Consisting of a pillar-crane mounted on a truck, and provided with a steam-engine capable of propelling and rotating the crane, and of hoisting and lowering the load.

Rectilinear Cranes may be classified as follows:

Bridge-cranes. — Having a fixed bridge spanning an opening, and a trolley moving across the bridge.

Tram-cranes. — Consisting of a truck, or short bridge, traveling longitudinally on overhead rails, and without trolley motion.

Traveling-cranes. — Consisting of a bridge moving longitudinally on overhead tracks, and a trolley moving transversely on the bridge.

Gantries. — Consisting of an overhead bridge, carried at each end by a trestle traveling on longitudinal tracks on the ground, and having a trolley moving transversely on the bridge.

Rotary Bridge-cranes. — Combining rotary and rectilinear movements and consisting of a bridge pivoted at one end to a central pier or post, and supported at the other end on a circular track, provided with a trolley moving transversely on the bridge.

For descriptions of these several forms of cranes see Towne's *Treatise on Cranes.*

HAND-OPERATED TRAVELING CRANES. — The weight of a hand-operated traveling crane depends not only upon the capacity of the crane and the length of the span, but also upon the particular design. The following approximate formula will serve as a rough guide when actual data are not available:

$$W = KCL,$$

where W is the weight of the crane in tons, C the capacity of the crane in tons, L the length of the span in feet and K a constant ranging from about 0.01 for $L = 10$ feet to 0.012 for $L = 75$ feet.

ELECTRIC OVERHEAD TRAVELING CRANES. — Electric traveling cranes usually have 3 motors, one for the hoist, one for the trolley traveling on the bridge and one for moving the bridge. Cranes of over 15 tons capacity are usually provided with an auxiliary hoist of from 1/10 to 1/3 the capacity of the main hoist. Automatic brakes are used to sustain the load when lifted and to regulate the speed when lowering, the hoist motor usually having to *drive* the load down.

Speeds of Electric Traveling Cranes. — The standard speeds at which the various parts travel in the cranes manufactured by Pawling and Harnischfeger are as follows:

STANDARD SPEEDS OF ELECTRIC CRANES, IN FEET PER MINUTE
(Pawling & Harnischfeger)

Capacity, tons (2000 lb.)	Hoisting speed, ft. per min.	Bridge travel, ft. per min.	Auxiliary hoist	
			Capacity, tons	Speed, ft. per min.
5	25–100	300–450	..	......
10	20–75	300–450	3	30–75
25	10–40	250–350	3 10	50–125 25–60
40	9–30	250–350	5 10	40–100 25–60
50	8–30	200–300	5 10	40–100 25–60
75	6–25	200–250	15	20–50
125	5–15	200–250	25	20–50
150	5–15	200–250	25	20–50

Trolley travel speed from 100 to 150 feet per minute in all cases.

Weight and Dimensions of Electric Traveling Cranes. — Let

C = capacity of crane, in tons (2000 pounds),
W_B = weight of bridge alone, in tons,
W_T = weight of trolley alone, in tons,
W = total weight of crane, in tons.

Then

$$W_B = K_B CL, \qquad W_T = K_T C,$$
$$W = W_B + W_T = C(K_B L + K_T),$$

where K_B and K_T have the following approximate values (*see paper by S. S. Wales, Proc. Eng. Soc. Western Pa., 1902, Vol. 18, p. 146*).

L	K_B	C	K_T
25	0.012	1–25	0.3
50	0.012	25–75	0.4
75	0.013	75–150	0.5
100	0.015		

For example, for a 50-ton crane for a 60-foot span, the bridge alone would weigh $0.013 \times 50 \times 60 = 39$ tons, the trolley would weight $0.4 \times 50 = 20$ tons, and the total weight would be 59 tons, approximately. If the bridge is equipped with 2 wheels at each end, the maximum load on each wheel when the trolley, carrying full load, is at the end of the bridge would be approximately

$$\frac{39}{4} + \frac{20+50}{2} = 45 \text{ tons},$$

or if there are 4 wheels at each end, the maximum wheel load would be 22.5 tons.

The following table is taken from a catalogue of the Alliance Machine Co.

DIMENSIONS AND WHEEL LOADS OF ELECTRIC TRAVELING CRANES

60-foot span and 25-foot lift; wire-rope hoist

Capacity, tons (2000 lb.)	Distance from runway rail to highest point		Distance from center of rail to ends of crane	Wheel base of end truck		Maximum load per wheel; trolley at end of bridge
	Feet	Inches	Inches	Feet	Inches	Pounds
5	6	0	9	9	0	20,000
10	6	6	10	10	0	27,000
25	7	4	12	11	6	51,000
40	8	0	12	12	3	82,000
50	8	9	12	12	6	48,000*

* Has 8 track wheels on bridge.

Standard cranes are built in intermediate sizes, varying by 5 tons up to 40 tons.

Power Required. — The following is adapted from the paper by S. S. Wales above referred to. The frictional losses will of course depend to a certain extent upon the design of the crane, the use of rope or chain, etc., but the constants given below represent fair averages.

The same notation as in the previous section is used. In addition let

R_B = tractive effort in pounds per ton required to move the bridge,
R_T = tractive effort in pounds per ton required to move the trolley,
S_B = speed of bridge in feet per minute,
S_T = speed of trolley in feet per minute,
S_H = speed of hoist in feet per minute.

Then the power required, at shaft of bridge motor, to drive the bridge at speed S_B is

$$P_B = \frac{(C + W_B + W_T)\, R_B S_B}{33{,}000} \text{ horse-power.} \qquad (1)$$

The power required, at shaft of trolley motor, to drive the trolley at speed S_T is

$$P_T = \frac{(C + W_T)\, R_T S_T}{33{,}000} \text{ horse-power.} \qquad (2)$$

The power required, at shaft of hoist motor, to drive the hoist at speed S_H, assuming 60 per cent efficiency of gearing and hoisting tackle, is

$$P_H = \frac{CS_H}{10} \text{ horse-power.} \qquad (3)$$

For *constant-speed running*, Wales gives the following values for R_B and R_T, the former varying with L and the latter with C.

L	R_B	C	R_T
25	30	1–25	30
50	35	25–75	35
75	40	75–150	40
100	45	......	....

If the moving member is *accelerating* at the rate of a ft. per sec. per sec., to the value of R given in the above table should be added an amount

$$R_a = 64\,a.$$

The power as calculated by the above formulas is the power *output* of the motors; to obtain the power input divide by the motor efficiency, which ranges from 80 to 90 per cent.

Motor Equipment.* — (*See also Motors, Industrial Applications of.*) Wales recommends that the bridge motor should have a rating (1-hour rating, the motors being rated on the same basis as railway motors) 1.5 times the calculated power for constant full-load speed, the trolley motor 1.25 times the calculated power for constant full-load speed, whereas the rating of the hoist motor should be taken equal to the calculated power for constant full-load speed. The motors may be designed for 110, 220, or 500–600 volts.

Both direct-current and alternating-current motors are successfully used for crane work. The series direct-current motor has speed-torque characteristics especially well adapted for crane service. At light loads the speed increases and at heavier loads the lifting is slower and the raising effect consequently stronger. This characteristic of the series motor often results in considerable saving of time, due to the fact that the majority of loads in factories are light, so that the increased speed of lift enables work to be performed in a shorter time. For a-c. motors a normal operating speed about 25 to 50 per cent higher than for d-c. motors is therefore generally selected and the slowing down for heavy work is accomplished by inserting resistance in the phase-wound rotor circuit.

Example. — Crane of 50-ton capacity, span 70 feet, bridge speed 200 feet per minute with full load, trolley speed 100 feet per minute with full load, hoist speed 15 feet per minute with full load. Then $C = 50$, $W_B = 45.5$, $W_T = 20$, $R_B = 40$, $R_T = 35$, and

$$P_B = \frac{115.5 \times 40 \times 200}{33{,}000} = 28 \text{ horse-power,}$$

and the motor required for the bridge would be $28 \times 1.5 = 42$ horse-power, or the nearest commercial size over 42, say 50 horse-power.

$$P_T = \frac{70 \times 35 \times 100}{33{,}000} = 7.43 \text{ horse-power,}$$

* By D. B. Rushmore.

and the size motor required for the trolley would be $7.43 \times 1.25 = 9.28$ horse-power, or say 10 horse-power.

$$P_H = \frac{50 \times 15}{10} = 75 \text{ horse-power,}$$

and a motor of this rating would be used for the hoist.

Control of Crane Motors.* — The control equipments for crane motors should be of the regulating and reversible type. The starting and speed regulation of series motors is generally accomplished by inserting resistance in series with the armature and field, and with induction motors, resistance is inserted in the phase-wound secondary or rotor circuit. For cranes which do a large amount of lowering, dynamic control is becoming very generally used, and is very readily accomplished with direct-current motors. It is also occasionally used with alternating-current motors, when direct current is available for excitation.

Drum Versus Magnetic Controllers. — Both hand- and magnetic-control equipments are in general use. The former are satisfactory for small and medium-size motors, and consist simply of a drum-type controller with a set of separate resistances. For large-size motors too much physical effort would be required to move a controller of the necessary size and the magnetic control should then be selected. A magnetic-control equipment consists of a master controller, a contactor panel and the resistances. The contactor panel contains the contactors for cutting in or out the resistances, the interlocks and the current-limit relays for automatically controlling the sequence and rapidity with which the contactors operate. The master-controller handle can be thrown to the full-speed position quickly without causing an overload on the motor, since the current-limit relays automatically prevent the contactors from cutting out the resistances too rapidly.

Dynamic Control. — With dynamic control of d-c. motors the field is separately excited and the armature is connected to the line voltage with one section of a rheostat in series with it, and another section of the rheostat in parallel with it. This is accomplished by means of the controller, whose duty is to make each step on the lowering side keep the speed of the motor under control no matter whether the motor has to drive a light hook downward or hold back against a heavy load. In the former case the current which passes through the series rheostat also passes through the armature and produces the desired torque. The speed is controlled by varying the value of this rheostat just as in hoisting. If the motor has to act as a brake, the power generated in the armature is expended in the parallel rheostat and the speed is controlled by varying this rheostat. In actual practice the two rheostats are varied simultaneously so that if a certain point on the controller tends to cause the motor to drive a load at a high speed it will also cause the motor to hold back at a high speed. The practical result is that an operator always has his load under control, and does not have to worry about dropping his load. On the lowering side of the controller, a motor holds back against its load even when power fails, because the motor then acts as a self-excited series generator, and consequently the solenoid brake alone is not depended on to prevent the load from falling.

In the case of a phase-wound induction motor it is necessary to excite one portion of the primary winding with direct current in order to generate a voltage in the secondary winding. A rheostat is then connected to the secondary windings of the motor and the speed can be controlled as with d-c. motors. As direct current is necessary for excitation dynamic braking is not very often used with a-c. crane motors.

* By D. B. Rushmore.

Solenoid brakes are also provided for holding the load when the hoist motor is stopped. If dynamic braking is not provided, mechanical brakes must be provided in addition to the solenoid brakes to assist in holding the load when the motor is stopped and for regulating the speed when lowering.

Solenoid brakes are, as a rule, applied by gravity when the armature current is shut off and released by the solenoid which is energized when the controller is thrown on the first notch. The solenoids of direct-current motors are generally connected in series with the motor circuit, although with polyphase induction motors they are connected directly across one phase thus receiving the full line voltage.

All crane motors should also be protected by safety-limit switches arranged to cut off the supply current when the limit of motion is reached and thus automatically provide against accidents from over-travel.

SPECIFICATION FOR ELECTRIC CRANE.* — The following memoranda are intended to assist in writing specifications. See also *Specifications.*

Principal Characteristics and Conditions of Service. — Span between crane rails and load to be lifted on main hoist and on auxiliary hoists, if any. Characteristics of current, a-c. or d-c. (phases, cycles and voltage).

Style and Description of Apparatus. — Structural work of open-hearth steel according to some standard steel specifications. Maximum stresses allowable. Whether hand operation is to be provided for. Distance of hook from crane rails, vertically and horizontally, when at extreme limits of its motion. Details of brake. Description and characteristics of motors to be supplied. Whether or not a foot-walk is to be supplied. Whether trolley is to be above bridge or submerged. Hoisting drum to have bronze bearings. Track wheels shall have chilled treads, ground true, with double flanges, and shall be keyed to their axles. Axle bearings shall be bronze. Details of lubrication and bearings. Location of carriage. Details of control. All gearing (except when shrouded) shall be cut, etc. Wiring details. Controller details.

Dimensions. — Supply a diagram of clearances.

Work Done by Other Contractors. — Track rail and weight thereof.

Performance and Tests. — Speeds of main travel, lateral travel and hoists. Time to get up speed or acceleration rates.

COST OF CRANES. — The cost of cranes depends to so great an extent upon the design, motor equipment, etc., that no reliable average figures can be given. As a rough approximation the cost of a hand-operated traveling crane may be taken as from about 5 to 7 cents per pound of total crane weight and the cost of an electric traveling crane as from about 10 to 13 cents per pound of total crane weight.

CROSS ARMS. — (*See also Poles for Overhead Lines; Insulator Pins; Insulators.*) Cross arms are usually of wood though sometimes of iron. "Buck arms" or "reverse arms" are cross arms attached to a pole at right angles to the principal arms, and are used for taking off wires at right angles to the line, either at the junction of intersecting lines or at services. "Double arms" are pairs of cross arms attached to opposite sides of a pole so as to act as one compound arm. Double arms are used to increase the strength of an arm and to permit the use of two pins and two insulators for supporting a single wire where additional strength is required.

Cross arms are used principally for supporting pins, insulators and wires, though lightning arresters, transformers, switches and other miscellaneous appliances are often mounted on them, usually for the purpose of keeping the pole free of incumbrances so that it will be more easy to climb.

Alley Arms. — When city distribution lines are located in alleys it is common to locate poles next to the property line. Where it is not permissible to let arms overhang private property special arms may be used which extend on one side of the pole only. These must be well braced and should not be used for dead ending wires. A better construction is obtained by locating two poles on opposite sides of the alley and putting special cross arms across the alley between them.

FORCES ON AND STRESSES IN CROSS ARMS. — The forces which a cross arm resists are:

(a) Vertical forces due to weight of pins, insulators, wires (with sleet) and accidental loads due to linemen standing on arms, etc.

(b) Transverse horizontal forces due to wind pressure on the wires (with sleet) at right angles to the line.

(c) Longitudinal horizontal forces due to the pull of the wires where the pull is unbalanced. Unbalanced pull is usually due to an angle in the line, the ending of the wire at the arm, a change in the size of wire at arm and an unequal tension in the spans on the two sides of the arm.

The principal internal stresses produced in an arm from these forces are:

(1) A bending force in a vertical plane due to vertical forces (a).

(2) A bending force in a horizontal plane due to horizontal forces (c).

(3) A twisting force about the longest axis of the arm due to the "pin leverage" of the horizontal forces (c). The pin leverage is the distance from the center of the wire to the axis of the arm.

Of these stresses the most destructive is probably the twisting stress which tends to split the arm in a vertical plane through the pin holes and along the grain of the wood. On this account the pin and insulator should be no taller than necessary, the pin should extend completely through the arm to give the best distribution of bearing pressure and, where stress is heavy, the arm may be strengthened by two "strengthening bolts" (machine bolts with nut and washers) put horizontally through the arm one on each side of the pin, one being near the top and the other near the bottom of the arm.

The vertical and horizontal bending stresses are of some importance and may be computed by the usual beam formula (*see Structures, Simple*). Data of tests on strength of cross arms for these stresses are given below.

Strength Tests of Cross Arms. — (*Forest Service, Cir. No. 204.*) Tests made on 3¾ in. by 4¼ in. by 6 ft., 6-pin air-dried cross arms with vertical load distributed equally at each pin hole gave the results at top of next page.

The tests showed that for ordinary use the strength, for vertical loads of 6-pin arms, need not be considered in calculations of line construction, except in the rare case of abrupt change of the grade of the line.

Kind of wood	Av'ge max. load in lb.
Longleaf pine, 75 per cent heart	10,180
Longleaf pine, 100 per cent heart	9,780
Shortleaf pine	9,260
Longleaf pine, 50 per cent heart	8,980
Shortleaf pine, creosoted	7,650
Douglas fir	7,590
White cedar	5,200

DIMENSIONS AND RATING. — Cross arms are rated in terms of the number of pins they are designed to carry, 2-pin arms being the minimum and 10-pin arms the maximum ordinarily used.

When arms are made directly from the original logs they are sometimes dimensioned in even inches, i.e., 4 in. by 5 in., 5 in. by 7 in., etc. In most cases they are made from lumber in stock and when finished are a quarter of an inch or more under the even sizes. Several "standard" dimensions have been adopted for distribution arms. In the accompanying table Standard I is that given by Miller (*American Telephone Practice*) and found in various catalogues of dealers in electrical supplies, Standard II is that given in Report of Committee on Overhead Line Construction of the National Electric Light Association, and Standard III is one used by the Stone & Webster Engineering Corporation. Fig. 1 shows a 6-pin cross arm according to Standard III.

Size of arms	Width, inches	Depth, inches
Standard I	3¼	4¼
Standard II	3½	4½
Standard III	3¾	4¾

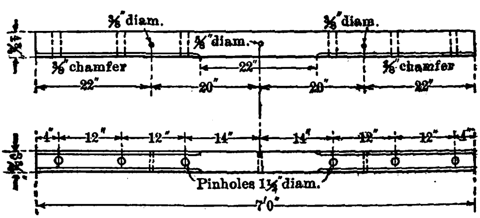

Fig. 1. Standard Cross Arms of Stone & Webster Engineering Corporation

Distance between Pole Pins. — It is desirable to have the space between pole pins (i.e., the two pins on opposite sides of the pole) as large as possible to give a clear space for climbing the pole. It usually varies from 16 in. to 30 in.

Distance between Other Pins. — This usually ranges from 12 in. to 21 in. Under ordinary circumstances 12 in. has been found sufficient to prevent wires on adjacent pins swinging in contact in the middle of the span. Where small wires (such as No. 10 telephone wires) are used on long spans (150 ft. or more) contact is to be expected occasionally where 12 in. spacing is used.

Distance from End Pin to End of Arm. — This is usually 4 in., which is about the minimum that can be used without the arm splitting due to pin leverage.

In order that a line may have a neat systematic appearance it is desirable that the pin spacing be the same for all arms, whether 2 pin, 4 pin, etc. In the tabulations below the arms included in each standard (defined above under *Dimensions and Rating*) have been grouped on this principle which shows that Standard I really consists of one regular group and 5 odd arms while Standard II consists of 2 regular and 1 odd arm. Referring to Standards I and III it will be noted that the length of arm is always a multiple of one foot.

STANDARD DISTANCES BETWEEN PINS

Standard	Group	Number of pins	Length of arm	End pin to end of arm	Between pole pins	Between other pins
			Ft. In.	In.	In.	In.
I	Regular	4	4 0	4	16	12
	Regular	6	6 0	4	16	12
	Regular	8	8 0	4	16	12
	Regular	10	10 0	4	16	12
	Odd	2	3 0	4	28	..
	Odd	4	5 0	4	18	17
	Odd	4	6 0	4	22	21
	Odd	4	6 0	4	24	20*
	Odd	6	8 0	4	18	17½
	Odd	8	10 0	4	17½	15¾
II	Regular	4	5 7	4	30	14½
	Regular	6	8 0	4	30	14½
	Odd	8	9 2	4	30	12
III	Regular	2	3 0	4	28	..
	Regular	4	5 0	4	28	12
	Regular	6	7 0	4	28	12
	Regular	8	9 0	4	28	12
	Regular	10	11 0	4	28	12

* Alternative found in some catalogues.

Pin Holes.—1½ in. diameter is standard for wood pins. N.E.L.A. specifications require that holes shall be tested with steel gauges taking one of the nominal size without forcing but not taking one 1/32 in. larger.

Bolt Holes.—For fastening the arm to the pole there is usually one ⅝-in. bolt hole at the middle of the arm. For fastening cross-arm braces there are two ⅜-in. bolt holes located 38 in. apart (Standard II) or 40 in. apart (Standard III).

High-tension Wooden Cross Arms.—These are not standardized but are specially designed and made as required. They differ from distribution arms in being wider and deeper with larger pin holes and wider pin spacing. The following tabulation will give data on some arms that have been used for different voltages.

Voltage	Number of pins	Width of arm	Depth of arm	Length of arm	Spacing of pins	Pin hole diameter
		Inches	Inches	Inches	Inches	Inches
25,000	2	6	6	64	48	2¼
55,000	2	5	7	88	72	2½

Special high-tension arms are usually unnecessary for circuits of 5500, 6600, 11,000 and 13,200 volts. Standard 2200-volt distribution arms may be used, the wire spacing being increased by not using certain pins. Thus a standard 2200-volt 6-pin arm may be used for a 11,000-volt 4-pin arm by leaving the middle pin holes vacant. For higher voltages the strength of arm and size of pin hole is usually insufficient.

SPECIFICATIONS. — *(See article on Specifications.)* The points to be covered in a set of specifications are:

Material. — Usually pine or fir, sometimes western hemlock. *(See Poles for Overhead Lines.)*

Quality of Material. — Usually should be "straight grained, free from knots (or free from large, loose or unsound knots), sapwood, pitch pockets, shakes, checks, loose heart, rot, worm holes or other defects." The strictness of the specifications, or of the inspection, must, however, be governed in these respects by local conditions. In some localities a quality of material can be obtained cheaply, and should be required, which would be unreasonable to expect where wood is expensive.

Wood should be dried before manufacture. (When arms are dried after drilling, the pin holes become elliptical, i.e., smaller across the grain, due to shrinkage of the wood and the pins do not fit well.)

Dimensions, Pin holes, etc., as noted in preceding section.

COST. — The cost of cross arms is subject to considerable variation and depends largely upon the locality in which they are purchased. The following figures are rough approximations and are exclusive of freight.

APPROXIMATE COST OF CROSS ARMS

Cents per linear foot

Kind	Washington fir, F.O.B., Seattle	Longleaf pine, "75 per cent heart," F.O.B., New Orleans	Commercial yellow pine F.O.B., New York
3¼ by 4¼ inches.....	5	6	5
3½ by 4½ inches.....	7	10	...
3¾ by 4¾ inches.....	8	...	...

In car load lots about 25 per cent less than above.

[R. A. PHILIP and CABOT STEVENS.]

DAMS. — (*See also Hydraulics; Hydrology; Power Stations; Structures, Simple.*) A dam is a structure built to interrupt a stream's flow and raise the level of the water, thereby impounding water which may be used for power development, water supply, navigation, irrigation or numerous other purposes.

Coffer-dam. — A dam built for the purpose of holding back water from an area, which would otherwise be flooded, and making it accessible for construction purposes, is called a coffer-dam. It is generally a temporary affair.

Diversion Dam. — This name has been applied to dams built for the purpose of diverting the whole or a portion of a stream into a side channel or race by which it is conducted to one or more places where it is used to develop power.

Wing Dam. — In swiftly flowing streams having steep slopes, a diversion dam is sometimes built out from one shore diagonally upstream toward the other, but not to it. This special form of diversion dam is known as a wing dam.

Gravity Dam. — Under this classification fall the many dams, all of which, although differing in form of cross-section, depend upon the force of gravity for resisting the thrust and overturning moment of the water. Earth and loose rock dams, timber cribs and most masonry dams are of this type.

Arch Dam. — These are built curved in plan, resting on the valley floor with the ends terminating in the valley walls which act as abutments to the arch so formed. Theoretically the arch dam should be safer and more economical than the gravity dam, but uncertainties in the theory of its action and design have made its use rare. In a long arch of large radius a certain amount of deformation must take place, before arch action can be developed, due to the elasticity of the materials and the fact that it was built under conditions of no stress. This would be a serious matter in any important dam since it would cause a slipping on the foundations or a rupture on other horizontal planes.

Composite Gravity and Arch Dam. — Often a gravity dam has been built in the form of an arch, using the possible arch action as a factor of safety, and depending wholly on the gravity action to resist the thrust of the water. Many of the highest dams in existence are so constructed and are generally in localities where the stream's valley is relatively narrow and deep.

LOCATION OF DAMS. — In power development the location of the dam depends largely on the topography and geological formation of the ground. In general it should be placed so as to produce the greatest fall at the least expense and insure perfect safety not only to the dam and power house, but to the country round about. A position should not be considered where ample provision cannot be made against possible disaster from log or ice jams and floods.

HEIGHT OF DAMS. — The height of the dam should be as great as possible in order to develop the power to its maximum extent. Care must be taken not to overflow lands not owned or controlled by the building company, neither must the rise in level set the water back on the wheels of another power development above the proposed one. Court cases and heavy damage suits are only too common in this connection.

MATERIALS AND FOUNDATIONS. — Stone masonry, concrete (plain and reinforced), steel, timber, loose rock and earth have all been used for dam construction either singly or in combination. Structural steel has been used only in a very few cases owing to the uncertainty of its durability. It does, however, offer the distinct advantage of permitting stresses to be more accurately computed and taken care of in the design.

Earthern Embankment. — The earthen embankment is the most common form of dam and generally the cheapest It can be safely built on foundations

that would not permit of masonry construction, but offers a decided disadvantage for power developments in that it cannot be over-topped with water without endangering the structure. This makes it in many cases an impossibility, since provision must always be made for flood-flows. When used, it is provided with masonry overflows or waste ways which require most careful design and construction.

Masonry Dams of considerable size require solid rock for a foundation. Small dams have been built on foundations of hard clay or compact sand, timber platforms being used to distribute the load.

Timber Dams may be used on any foundation and generally consist of cribwork filled with rock, sand and clay planked over to make it fairly tight. If placed on soft bottom, piling is sometimes used for a support and sheet piling driven vertically into the bed to prevent seepage. Timber dams are often placed on rock foundations in which case they are bolted in position.

Loose Rock Dams, as the name implies, are embankments of loose rock made partially impervious by a core or facing of earth or other fine material. Since percolation through the dam is possible, the foundation must be safe against scour and, if the dam is of considerable height, should be solid rock.

Rock-filled Dams are not extensively used for power development because of the relatively large loss of water by seepage.

DESIGN AND CONSTRUCTION OF EARTH DAMS.—The materials used are loam, sand, gravel and clay mixed in various proportions, the clay being used to make the other three impervious. The earth dam is generally trapezoidal in section, having a top width and side slopes which are determined by the materials used. It may be built either with or without a core wall, the object of which is to offer an impervious barrier to seepage. When no core wall is used, the whole embankment may be constructed of uniform material mixed and placed so as to be as near water-tight as possible, or the material may be sorted and the best and most impervious placed in the upstream embankment and near the face, with a gradual change to the coarser and more porous material as the lower face is approached. Even with the core wall this method is often followed.

Core and Foundation for Earth Dams.—Since the core is used to obtain imperviousness, its use is imperative only when good material is not at hand or abundant. Cores are most often built of clay puddle, carefully mixed and rammed, but have been constructed of fine earth, and often masonry cores are used. The thickness of a puddle core is ordinarily 4 to 8 feet at the top, and at the bottom about one-third the water depth. Masonry cores can be made thinner in good embankments and generally have a top width of from 2 to 4 feet with side batters of ½ to ¾ inch per foot down to the trench. In all cases the core should reach down into the foundation to a stratum of compact, impervious material and several feet into it. Stiff clay or hardpan makes the best foundation and solid rock is also good if free from cracks and fissures.

Side Slopes and Top Width of Earth Dams.—The slopes given the embankments vary considerably in practice, but in general are about the same for the two faces. The upstream face is usually protected by rip-rap or paving and the slope is about the natural angle of repose. With coarse material this may be 2 horizontal to 1 vertical but with fine material it is sometimes 2½ or 3 to 1. The amount of material in the lower embankment has much to do with the stability of the dam, consequently flatter slopes are used here than the drier, more porous material would necessitate. A slope of 2 to 1 is commonly used. The top width of the embankment is often determined by re-

quirements for a roadway. Where not so fixed it may be made proportional to the height and determined approximately from the relation,

$$w = \frac{h}{5} + 5,$$

where h is the height. High dams with long slopes are liable to rain-scour on the lower face unless provision is made for draining off the water. This can be done by building berms a few feet wide every 30 feet or so on the slope, thereby providing lateral drainage. To protect the upper face from ice and wave action the slope is paved with a hand-laid pavement 12 to 18 inches thick laid on 6 to 12 inches of broken stone or gravel. Heavy rip-rap is often used below the water line.

Procedure in the Construction of Earth Dams. — In preparing the foundation the surface soil is stripped to a depth sufficient to reach sound material, and all loose stones, stumps, roots, etc., removed. If the foundation be rock, the surface is cleaned and roughened to aid in making a good bond with the earth. The core wall (if used) is started in its trench and when it is even with the surface, or a little above it, the embankments are begun. The material is put on in layers 6 to 12 inches thick and rolled with a grooved roller after being sprinkled with water. If a puddle core be used, it is carried up along with the embankments, but a concrete or stone core must be kept several feet above them and the earth should be rammed well against it.

MASONRY DAMS. — Both stone and concrete have been widely used in constructing masonry dams. Recent practice has favored concrete and many of the highest dams have been built of it. It is often cheaper to obtain than stone, may be economically handled, and, if well laid, presents a homogeneous mass with no joint planes or weak spots to offer chances of slipping or crushing. "Cyclopean masonry" is concrete containing large stones or "plums" carefully placed in the wet concrete so as to be entirely surrounded by it. Stones with a content of 1 to 2 cubic yards are not uncommonly used, and economy results. In the last ten years or so, many important dams have been built of reinforced concrete with gain not only in economy but in convenience and in certainty of design.

Foundations for Masonry Dams. — Most masonry dams over 30 feet in height require solid rock foundations. From this all soil and disintegrated rock is removed and the surface scrubbed clean. All cracks and fissures at the site and for some distance above and below it must be located and grouted under pressure. If originally smooth or inclined the rock is roughened or stepped off to offer a good bond between it and the masonry. Often a longitudinal trench is blasted out, into which the masonry may be carried to form a cut-off wall for any water seeking a way under the dam. This is generally placed at the upstream face or heel of the dam. (*See Fig. 1.*)

Where low dams are built on earth foundations, the earth should be hard clay or compact sand of an even texture. Plank foundations on piles are sometimes used to distribute the load, and sheet piling is often driven into the foundation at the upper edge of the dam to prevent seepage. It should reach down to a stratum of impervious material, or deep enough to make percolation under it a slow process.

General Principles of Design of Masonry Dams. — (*See also Structures, Simple.*) The chief forces considered in the design are gravity, water pressure, ice pressure and temperature stresses. If water percolates beneath the dam, upward pressure is developed which, if not taken care of, may ultimately be the cause of the dam's destruction. If considered in the forces acting, it will result in an exaggerated and uneconomical section. Upward pressure is best

avoided by using all possible care in making the foundation work tight and by providing underdrains. *(See below).*

Temperature Stresses generally show their action by a series of vertical cracks in the face of the dam. In massive structures it is probable that the temperature of the interior material changes but little during the year and that only the outer shell is subject to these strains. Little attention is generally paid to temperature stresses in any but large dams, where allowance is made by considering that the first few feet of outer shell may not be so effective in adding to the stability of the whole as the inner core.

Ice Pressure may be very great under some conditions but cannot be well estimated. The thrust from surface ice cannot well exceed its crushing strength, which may be taken at 400 lb. per square inch, yet it is difficult to see how this may be exerted. The chief danger comes from a "shove" of broken cakes piled against the dam and urged over it by a rise in the stream. The forces developed under these circumstances may be very great and the best protection against them is obtained by shaping the top of the spill-way so that the ice may ride easily up and over it.

Fundamental Conditions. — When the following fundamental conditions are fulfilled the stability of any masonry dam will be assured:

(*a*) No pressure to be allowed on any joint * or in any part of the dam greater than the safe working pressure. This varies from 8 to 15 tons per square foot according to the material.

(*b*) No tension to be allowed on any joint. Assuming that the stress varies uniformly over a joint, it can be shown that if the resultant pressure on any joint falls within the middle-third portion of the joint,† no tension can exist. The condition of no tension is, therefore, that on every joint the resultant force must lie within the middle third of the joint.

(*c*) At each joint the resistance to shear or to sliding shall be greater than the shearing force. If the dam be constructed with no continuous horizontal joints, and in accordance with conditions (*a*) and (*b*) above, sliding will be impossible save at the foundation. If the latter be rock it should be roughened or stopped to obviate a continuous plane joint. On other foundations the angle that the resultant force makes with a vertical line should not exceed the angle of repose of masonry on the material composing the foundation.

(*d*) The dam as a whole must resist overturning. If conditions (*a*) and (*b*) be fulfilled the dam will have a factor of safety of at least two against overturning.

Types of Cross-Sections or Profile. — Cross-sections differ in profile principally according to whether or not the dam is to pass water over its top. Where it does not, the type shown in Fig. 1 is fairly representative. If it does, then the rounding top and curved face shown in Fig. 2 is commonly used, although on rock foundation it may not be necessary to add the lower curve to the face, or down-stream side, which is for the purpose of deflecting the water and protecting the foundation. The upper portion of the curve is usually made parabolic to conform to the natural path of the water as it leaves the crest with an initial horizontal velocity and falls freely under the action of gravity. If the descending sheet or nappe does not touch the dam, partial vacuum will occur behind it and the atmospheric pressure on the back, or up-stream side, of the dam will become effective as an overturning force.

* By joint is meant any plane section through the dam, or portion of such a section, whether there exists an actual joint in this plane or not.

† Imagine a horizontal line in any cross-section of the dam, and let this line be divided into three equal parts; the middle part is called the middle third of the joint in which this

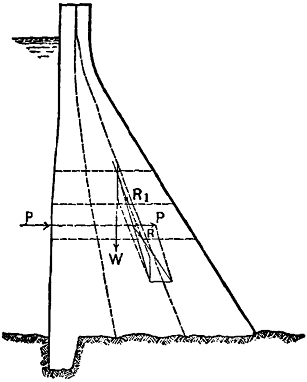

Fig. 1.

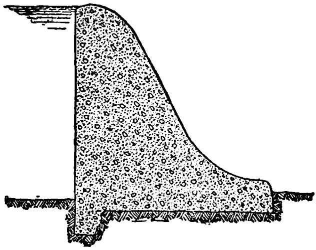

Fig. 2.

Calculation of Dimensions of Cross-Section. — The proportions of the section are possible of mathematical determination once the forces become known. Wegmann, in his *Treatise on Dams*, gives the equations (and their derivation) necessary for the different steps. A more common method is the "cut and try" by which a profile is first assumed and then investigated with regard to the conditions of stability (*a*) to (*c*) as stated above. It is then corrected and again tested until it results in a section satisfactorily strong and yet economical. Fig. 1 shows the steps and result of this method. Starting with a given height, top width and unit weight of masonry (*see Weights of Materials*), a series of horizontal joints are arbitrarily assumed at equal distances through the structure. The position of the resultant force on each joint is graphically found by combining the resultant force on the above, or previous joint, with the weight of the masonry block between joints, and the water pressure on the back face of that block. Starting with the top block, where the weight and the water pressure are the only forces, this is easily accomplished. If the "line of resistance," i.e., the line which connects the points of application of the several resultants falls at any point outside the middle third portion of the section, the profile is changed and a new "line of resistance" drawn.

Calculation of Maximum Pressure on a Joint. — The maximum pressure on any joint (according to the usual assumptions, which are justified by experience) may be found from the relation

$$P_{\max} = \frac{V}{l}\left(1 + \frac{6e}{l}\right) \qquad \text{pounds per square foot,}$$

where V is the vertical component of the resultant force in pounds (per unit length of dam) on that joint, l the length of the joint in feet (the horizontal distance perpendicular to the length of the dam from the face to the back of the dam), and e the distance in feet from the resultant to the centre of the joint. It can be shown that a dam constructed to satisfy condition (*b*) above will be safe against crushing if the height is not much over 100 feet.

Effect of Water on Crest. — When water is passing over the dam extra forces are developed which tend to make the dam less stable. The pressures arising from the dynamic action of the water are generally disregarded and the pressures on the back of the dam are considered to be due to the head of water whose level is that of the water going over the crest. No allowance is

made for the effect of the weight of the water as it flows over the down-stream face.

Underdraining. — In many large and important dams, provision against upward water pressure has been obtained by placing a system of drains in the foundation. They may lead to a main sump in the structure or directly to the outside at a point in the toe of the dam. Their more general use would seem to be a part of good design.

REINFORCED CONCRETE DAMS. — The last few years have seen the rapid development of reinforced concrete in dam construction. Most dams so built consist of an inclined decking of reinforced slabs, resting on a series of parallel buttresses which have their footings in the foundation. Fig. 3 shows the section of such a dam designed to pass water over its crest. With a low dam and rock foundation, the down-stream decking or apron may be omitted and the face made vertical. The great stability of the dam follows from the fact that the water pressure is inclined and, when compounded with the weight of the dam, gives a resultant pressure on the base which is nearly vertical. Fig. 3

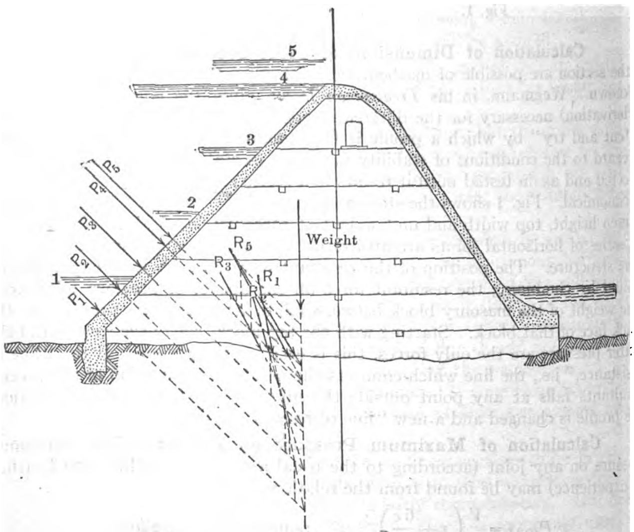

Fig. 3.

shows this resultant to change little in position as the height of water behind the dam changes, a condition far different from that existing in the solid dam as generally designed.

Advantages of Reinforced Concrete Dams. — There is no doubt that this type of structure possesses certain marked advantages. The stresses developed may be calculated with considerable certainty and the structure properly designed to meet them. The temperature stresses are provided for by expansion joints in the deck slabs placed at each or every other buttress. Ice cannot exert its full strength as the face of the dam is inclined and raises the ice. The dam may be easily inspected at all points when in service, and from the manner

of its construction affords simple means for accomplishing the final "closing" of the dam. Not the least of its good points is the practical elimination of chance for upward pressure.

Disadvantages of Reinforced Concrete Dams. — Against all these advantages may be urged the uncertainty of the life of steel reinforcement in concrete under water, and it is this fact that has prevented its wider adoption. A majority of dams so built have been constructed by or from the designs of the Ambursen Hydraulic Construction Co., and to date (1914) no failure has occurred, even of a partial nature. An examination of the steel in a dam 10 years old has revealed no trace of oxidation, or deterioration.

APPENDAGES TO DAMS. — The more common appendages to dams are the following:

Sluice Gates. — As their name implies, these are large gates placed in the dam for the control of the water level, or for relieving the dam in times of flood. A common type of gate is the so-called Tainter gate which is slightly curved and revolves about its axis of curvature. A later improvement on this is the Hall gate which permits of finer regulation.

Flash Boards. — These are light boards, or their equivalent, placed on the crest of the spillway and held in position by light rods or frames. Their object is to temporarily increase the height of the dam during the dry season so as to conserve the water which would otherwise be wasted over the spillway at times when the wheels were not running. They are made light not only to facilitate handling, but also that they may give way quickly in emergency before a dangerous head could be created by sudden flood.

Log Runs. — On any stream where the driving of logs is practiced, it is generally a requirement that provision be made in a dam for the sluicing of logs. This is accomplished by a chute or trough placed generally near the spillway, with its upper end slightly below the pond level and closed by a sluice gate. To this the logs are guided by log booms fastened to the dam and cribs along the shore.

Fish-ways. — A fish-way is a gradual incline connecting the water below the dam with the pond above. A constant stream of water passes through it with a velocity against which the fish may readily swim. This is sometimes attained by using baffles across a portion of the stream, leaving a passageway at the side. The slope of a fish-way should not be greater than 1 in 4 and its ends should be well beneath low water level. Fish-ways are generally more or less covered in order to protect the fish from interference, but should never be made dark, as they would not be used by the fish. Fish-ways are generally required by State law on all natural water ways.

COST OF DAMS. — It is difficult to give items of cost for dam construction, due to the great influence of local conditions. As earth embankments should not be attempted in places where material is not available near the site, the figures for unit cost may be fairly well approximated. Excavation in earth will cost from 20 to 30 cents per cubic yard; embankment 25 to 40 cents; puddle cores 45 to 70 cents; hand-laid paving \$2.00 to \$3.00; rip-rap \$1.50 to \$2.00; sodding 20 to 30 cents per square yard. Figures for masonry dams depend largely on the ease with which the materials may be brought to the site. The following figures serve to show approximately the unit costs under conditions normally favorable. Rock excavation \$1.00 to \$2.00; rubble masonry laid in natural cement \$3.00 to \$5.00; same laid in Portland cement \$4.00 to \$6.00; concrete masonry, Portland cement, \$5.00 to \$7.00; reinforced concrete \$7.00 to \$11.00; rock-faced stone masonry \$10.00 to \$15.00; dimension stone masonry \$15.00 upward.

BIBLIOGRAPHY. — Some of the more important modern books treating of dams are the following: Wegmann, *Design and Construction of Dams*, N. Y., 1907; Mead, D. W., *Water Power Engineering*, N. Y., 1908 (contains an extended bibliography to 1908). The following are recent articles in the technical journals dealing with the design and construction of dams.

DEMAND INDICATORS. — (*See also Ammeters; Ampere-hour Meters; Watthour Meters.*) For some time past various attempts have been made to inaugurate systems of charging for electric energy which would be more equitable to both the consumer and the central station than a flat kilowatt or kilowatt-hour rate. The so-called "maximum demand system" has found favor with many, and may find a much more general application.

The system is based on the fundamental assumption that the charge to any consumer should be divided into two parts: one part fixed by the maximum power demanded by an individual consumer at any time during a certain definite period, and another part fixed by the total number of kilowatt-hours used during the same period.

Requirements of a Demand Indicator. — The kilowatt-hours supplied to the consumer are readily measured and recorded by a watthour meter (q.v.); to record the maximum power (kilowatts) taken by the consumer various forms of "maximum demand indicators," usually called simply "demand indicators," have been devised. In the case of a practically constant d-c. voltage at the consumer's premises, a device which measures the maximum current is as satisfactory as one which measures maximum power, but when the voltage or power factor (in case of an a-c. system) varies, the maximum current indicator is not suitable.

In any case the device should be one in which the demand measured is not the instantaneous peak of the load demanded by the consumer, but is the average of the power demanded over an appreciable time interval, for the maximum demand recorded should not be influenced by short-circuits, excessive current flow in starting motors, or by any abnormal consumption of energy that covers too short a time to have any real effect on the capacity which must be provided in the central station to take care of the demand.

The time over which the demand should be taken differs with the character of the installation and its relation to the maximum power demanded and to the maximum capacity of the central station. In relatively large consumers' installations the time should be carefully chosen with reference to the time that the central station can endure an overload successfully. In small installations, such as residences, the time interval is not important, provided it is long enough to cover any abnormal and sudden fluctuations of load, but not longer than the ordinary period of sustained maximum load. In some instances times as short as one or two minutes have been selected for large installations, and about fifteen or thirty minutes seems to be quite generally satisfactory for household installations and small industrial plants.

In connection with demand systems of charging it is sometimes of advantage to know at what time of day the maximum demand occurs, for it is sometimes possible to give preferential rates to large consumers if they will draw their heaviest load at periods when the station load-curve is below its maximum.

The general subject of demand indicators has received considerable attention within the past year or two and many new devices have been developed experimentally, and will no doubt soon be on the market. The whole system of charging, including the necessary devices to be used, may be considered to be in a transition state. Some of the demand indicators now in commercial use are briefly described below.

Curve-drawing Wattmeter as a Demand Indicator. — (*See also Wattmeters.*) The most accurate method of obtaining a complete knowledge of the conditions prevailing on a customer's premises is to use a curve-drawing wattmeter. With this device the average demand over any period of time can be taken, and the time at which the maximum occurs may be definitely known. However, curve-drawing wattmeters are too expensive and troublesome for any

but comparatively large installations, and one of the cheaper and simpler devices described below is ordinarily used.

TYPES OF DEMAND INDICATORS. — The devices, which have so far been produced, may be divided into the following classes: (1) Instruments in which the time of reaching the maximum record is delayed, and in which the maximum record and time over which it is averaged depends more or less on the previous load conditions; (2) Instruments in which the time over which the demand is averaged is definite, the period of registration beginning and ending at certain definite times controlled by a clock or equivalent device.

In either of the above types the record may be obtained by automatically pushing a pointer up the scale and leaving it at the maximum indication, in which only the maximum is recorded, or various arrangements of moving charts may be employed on which any number of records may be made. In some cases the time of each record is also indicated, in which case the instrument may be nearly equivalent to a curve-drawing wattmeter, provided the time interval over which the average is taken is short.

Wright Demand Indicator. — This instrument, manufactured by the General Electric Company, records the maximum ampere demand of appreciable duration in either a direct- or alternating-current circuit. It operates on the principle of a differential air thermometer. The instrument consists principally of an enclosed system of a vertical U-tube with unequal arms and with nearly equal bulbs at the ends, Fig. 1. An indicating tube of uniform bore is annealed to the shorter arm of the U-tube just below the bulb b_2. The upper bulb b_1 is closely surrounded by current-carrying heater strips wound non-inductively. The U-tube is filled with sulphuric acid and both bulbs with air, in such a way that the air in the upper bulb b_1, heated by the electric current in the strips, causes some of the liquid to flow into the index tube i_2 and to remain there as a record until the indicator is set back. The system of tubes and bulbs is fastened to a frame which can be turned up slightly more than 90°, so as to allow any liquid contained in the index tube to flow back into the bulb and U-tube. Since the expansion of the air in the heated bulb b_1 is approximately proportional to the final rise of temperature, and hence roughly proportional to the square of the current in the heater coil, the ultimate height of the liquid in the index tube i_2 will be proportional approximately to the square of the current in the heater strips. The scale reads directly in amperes.

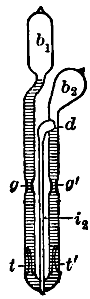

Fig. 1. Wright Demand Indicator

Wright demand indicators of all capacities from 5 to 150 amperes inclusive may be connected directly into alternating-current circuits of any commercial frequency. Indicators of 200 amperes capacity and over are furnished with shunts for direct current and with current transformers for alternating current.

The Wright demand indicator is not suitable for the determination of maximum loads in alternating-current circuits of variable power factors. It leaves no record of the duration of the maximum demand nor of the time at which it takes place. After the instrument has been reset there is no original record of previous maximum demands.

Time Lag and Precision of Wright Demand Indicator. — Each instrument has its individual time lag, and the same instrument may have different time lags at different loads. The time lag is shown by the following average figures: 90 per cent of any increase of load is indicated after approximately 4 minutes' duration, 97 per cent after 10 minutes, 100 per cent after about 40 minutes. Wright demand indicators are sufficiently accurate for most com-

mercial installations, provided they are installed in locations which are not subject to abnormal temperature variations.

Type W Polyphase Demand Indicator. — This instrument, made by the G. E. Co., is suitable for indicating loads and for recording maximum loads on polyphase alternating-current circuits in which these loads have appreciable duration. The time lag, which for this instrument is defined as the number of minutes required for the meter to indicate 90 per cent of any change of load, may be adjusted from one to five minutes. With the time lag adjusted for five minutes, full deflection corresponding to a change of load is reached after about 15 minutes. The instrument is constructed on the principles of a polyphase induction watthour meter (*see Watthour Meters*). Fig. 2 shows the arrangement for a 3-wire, 3-phase instrument. Both current and both potential elements act on the upper disc D_1. A system of controlling springs at S provides a restoring moment, the springs being adjusted so that full-load driving torque will be completely balanced by the restoring moment of the springs at S when the vertical shaft has made three revolutions, corresponding to one revolution of the indicating pointer H_1, driven by means of a system of gearing of 3:1 ratio. The other pointer H_2, driven by the first one, is held at the maximum position reached by H_1 by means of a ratchet and remains there until set back by hand. The propelling torque is proportional to the power in watts and the restoring torque is proportional to the deflection of the moving system, therefore the ultimate deflection of the pointers is directly proportional to the power in watts. The magnets M and M' acting on disc D_2 provide an exceedingly heavy damping system. The indicator is thereby prevented from recording power demands of short duration. The type W polyphase watt demand indicator is made in all standard capacities. For the larger capacities instrument transformers are used in the same way as with the watthour meters. The instrument leaves no record of the duration of the maximum demand nor of the time at which it takes place.

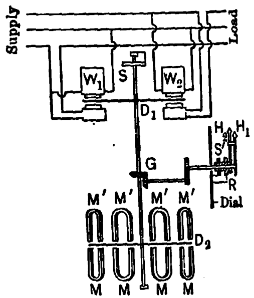

Fig. 2. Type W Demand Indicator

Precision of Type W Demand Meters.— Most of the advantages and the limitations of polyphase induction watthour meters apply to this instrument, and, in addition, it is extremely delicate, and its operation may be affected by mechanical shocks and jarring.

Combined Watthour and Demand Meter, Single Phase. — This instrument, made by the Westinghouse Electric and Manufacturing Co., is a combination of induction watthour meter, induction wattmeter, and an escapement form of time element. The time for this instrument to reach maximum deflection corresponding to any change in load is constant, provided the load remains constant during this time interval. The meter records, besides the kilowatt-hour consumption, the maximum load in watts in the circuit. The instrument leaves no record of the duration of the maximum demand or of the time at which it takes place.

Demand Indicator Attachments to Watthour Meters. — These devices are on the market in various forms and under various names and are used to indicate the average power over a certain predetermined period of time. All of them depend for their operation on a device the speed of which is proportional

to the rate of energy consumption in the circuit, and on a clock or some equivalent constant-speed device by which the time interval is determined over which the average power demand is desired. Consequently these devices may be applied to any circuit in which a watthour meter will correctly measure the energy consumption. The accuracy of any particular device of this kind depends, therefore, on the accuracy of the watthour meter in connection with which the attachment is used, and on the accuracy of the constant-speed device which determines the time interval. Among these demand indicator attachments may be mentioned the Maxicator, Printometer and Graphometer made by the Chicago Electric Meter Co.

Maxicator. — The maxicator is used for the purpose of indicating the largest half-hourly average of power demand. It consists of a register element and a contact making motor or clock. The register element operates as an ordinary gear train of a watthour meter and has connected with it through a special train of gears a driving element which engages with the maxicator hand on a special dial. This hand is carried forward at a rate proportional to the speed of the watthour meter and therefore proportional to the rate of consumption of energy in the circuit. At the end of each interval of thirty minutes, the contact making motor or clock will cause a solenoid, connected to the driving element, to be energized in such a way as to reset the driving element to a zero position. The maxicator hand is thus left at the point which it had reached after the first half-hour interval. The resetting operation is so arranged that it does not affect the regular dial pointers of the register. The driving element after having been reset revolves as before, but does not re-engage and drive the maxicator hand unless the energy consumption in the second half hour exceeds that of the first half hour. Thus the distance moved by the maxicator hand is proportional to the watt-hours for a period of thirty minutes. The maximum half-hourly average of the power demand in watts is obtained by dividing the reading in watt-hours of the maxicator dial by the time interval.

A constant-speed motor is preferable to the clock for making the half-hourly contacts, as the former reduces the cost of inspection and attendance; on the other hand, the clock may be made to operate with greater accuracy than a motor. The maxicator hand is reset by the meter reader, who thereby destroys the original record of the maximum demand. The duration of the demand and the time at which it occurrs cannot be obtained by the maxicator.

Printometer. — This instrument is designed to print on a paper tape at regular time intervals the time of record and the consumption of energy up to that time, the energy consumption being that registered by a watthour meter connected to the circuit. The instrument contains a set of cyclometer type-wheels which are moved forward at a rate proportional to the rate of energy consumption in the circuit. This is accomplished by a solenoid, the energizing circuit of which is closed through a contact wheel fixed to one of the spindles of the gear train of the watthour meter. The reading of the cyclometer is printed, at regular time intervals, on a slowly moving paper tape by the agency of a rubber platen and a copying ribbon, the rubber platen being actuated by a solenoid which is energized at regular time intervals by means of a contact making clock. The time is also printed opposite each cyclometer reading. Thus, the difference between consecutive records on the tape is proportional to the energy consumption in watt-hours in the circuit during a definite time interval. The average demand over a period of time, corresponding to the interval between successive operations of the printing solenoid, is obtained by dividing the watt-hours of energy consumption during a time interval by the length of the interval.

This device, therefore, gives an original record of a permanent nature, which furnishes complete data for a continuous load curve for the circuit to which it is connected.

Graphometer. — The graphometer is designed to draw a curve showing average demands for successive time intervals of equal length. The principle of operation of the graphometer is similar to that of the printometer, described above. The plunger of a solenoid, the energizing circuit of which is closed through a contact wheel fixed to one of the spindles of the gear train of a watt-hour meter, causes a stylus to be moved vertically upward a distance proportional to the number of contacts made by the contact wheel, and hence proportional to the energy consumed in the circuit. The stylus draws a line on a treated paper chart which moves uniformly in a direction at right angles to the direction of motion of the stylus. At the end of the interval for which the contact-making clock is adjusted, the mechanism driving the stylus is caused to become disengaged from the rack carrying the stylus, which is thereby allowed by gravity to drop back to a point corresponding to the zero position on the chart, when the same series of operations begins for the next interval. The various ordinates on the chart represent average power demands for a definite time interval.

The graphometer therefore plots directly the points for a continuous load curve, which serves as a permanent record, and which requires no interpolation, and from which the maximum demand may be read at a glance with the aid of a suitable scale.

Costs. — The net prices of the different types of demand indicators are as follows:

Type	Description	Price
Wright Demand Indicator	5 to 150 amp. for 750 v. and below...	\$5 to \$12
Wright Demand Indicator	D-C. only, 200 to 600 amp. for 750 v. and below........................	10 to 17
Wright Demand Indicator	A-C. only, 200 to 600 amp. with current transformers up to 2300 v....	35 to 40
Type W Demand Indicator	5 to 75 amperes, 110 to 440 v........	75 to 80
Watthour Demand Meter	....	20 to 25
Maxicator.................	15 to 30 min. time interval.........	21
Graphometer..............	....	45
Printometer...............	....	115 to 160

[L. T. ROBINSON AND O. R. SCHURIG.]

DEPRECIATION. — Depreciation may be defined as a decrease of value due to deterioration, loss of useful association, obsolescence, inadequacy, and a general change in the level of prices.

VALUE. — Value is a ratio or number expressing the relative quantities of commodities or services which are considered equal in exchange. It is not an intrinsic quality of matter like mass or length, but an extrinsic quality or relation like height or electric potential. In other words the value of a property must not be sought in the property itself but in its relations to other properties and services. Value is a function of demand and supply which in turn depend upon utility, scarcity, beauty, cost of production, and many other circumstances. For a discussion of the nature and various elements upon which value depends, see *Science of Money*, by Alex. Del Mar.

The value of public utility corporations often has to be estimated in order to furnish a basis for the determination of rates or charges for services, assessment of taxes, limitation of security issues and fixing prices for purchase or sale.

FACTORS AFFECTING DEPRECIATION. — As already noted the factors affecting depreciation are deterioration, loss of useful association, obsolescence, inadequacy and a general fall in prices.

Deterioration may be defined as any change in a property due to wear and tear or the ravages of the elements, which tends to impair either its usefulness or its life.

Loss of useful association may be defined as any change in the associations of a property, which tends to impair its usefulness or life.

Obsolescence may be defined as loss of commercial utility in any property, due to the advent of superior substitutes.

Inadequacy is loss of commercial utility in a property due to its inability to meet increased business conditions.

Deterioration can be approximately predetermined from the results of previous experience, while loss of useful association, obsolescence and inadequacy are of a more speculative character and less amenable to computation. Variations in the general level of prices are also impossible to predict. While, therefore, it is possible to estimate with some degree of accuracy how much it will cost to overcome deterioration, it is possible only to bet or insure against obsolescence, loss of valuable association and the results of monetary instability.

METHODS OF APPRAISAL. — A property in its entirety can have only one value at a given time and place, although of course different parts have different values, and it may be that for some purposes for which valuations are made only part of the value has to be considered. Thus by omission of certain elements, figures may be obtained called tangible value, intangible value, fair value and so on. They are really partial values, and not different kinds of values. The true value of a property appears only when it is bought or sold, although it exists at all times. There are, however, many occasions when it is necessary to know the value of a property without putting it on the market, and, for this purpose, estimates of value or appraisals have to be made. Considerable difference of opinion exists, however, as to the proper way to estimate value, some writers even referring to the different kinds of estimates as different kinds of values, which is obviously inaccurate.

Market Value. — There are two different ways of estimating the value of a property. One is by taking into account all the elements which would affect its salability, and estimating what a responsible bidder would offer for it.

This gives what is called the market value. It is not a value, but merely an estimate of value by a particular method. The other way of estimating value is by calculating the cost of reproduction of the property. This gives what is called the reproduction value. This again is not the value, but merely an estimate of value by another method.

Reproduction Cost. — The market-value method of appraisal is useless as a basis for rates because the market value itself is determined by the rates. It is therefore usual to estimate value by the reproduction-cost method. Unfortunately this method has been applied in two different ways. By some authorities, cost of reproduction is taken to mean the cost of a substantially identical reproduction of the existing plant. They do not mean that apparatus of antiquated pattern will be exactly duplicated but assume it to be replaced by the nearest modern substitute. According to other authorities, cost of reproduction may mean the cost of a substitute plant of the most modern approved design capable of performing the same service as the existing plant. If the old plant were wiped out, what would it cost at present to construct a plant capable of performing the service now performed by the old plant? In the case of a water plant, perhaps an entirely new source of supply would be used and the distribution system radically changed.

In either case, the present value of the old plant is measured by the cost of an equally efficient new plant less an allowance for the depreciated condition of the old plant. It is obvious that there is no definite distinction between the two interpretations, the difference arising principally in the different degree to which obsolescence is taken into account as an element of depreciation.

Court and Commission decisions in relation to valuation have not yet become uniform and authoritative, showing that the subject of valuation is in a developmental stage. Perhaps the general tendency is toward estimating value by the reproduction-cost method, making the reproduction in the most modern manner.

PRESENT VALUE. — The value of a property can appear only in a purchase or sale, but it exists at all times. Hence some means must be devised to estimate how depreciation affects the value of a property between the time of its purchase and its sale.

In default of a true measure of value during this period, various arbitrary scales have been devised. This can best be explained with the aid of a diagram, Fig. 1, having for ordinates, value in dollars, and for abscissæ, time in years. On this diagram, let the ordinate of the point A represent the replacement cost when the property is in its best physical condition, and the ordinate of the point B the net proceeds resulting from the sale of the property at a time OP years later. It is obvious, that any curve joining A and B, which is confined between the lines AC and DB and never turns back, may be arbitrarily adopted as the curve of value during this interval.

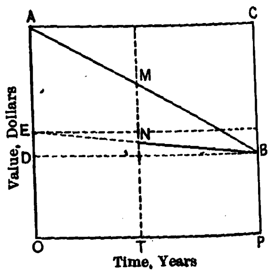

Fig. 1

Various people have suggested different shapes of curves, but the most common practice is to assume A and B to be joined by a straight line. Curves other than straight lines, which have been suggested by various people, have often been curves of utility and misnamed curves of value. Such curves of utility are meaningless, first because utility cannot be measured by money,

and second, because value is not necessarily proportional to utility. Utility is only one of many factors which affect the value of a property.

The shape of the curve of value being arbitrary, it is obviously most simple to assume it to be a straight line, as shown in Fig. 1. The "present value" of the property at any given time is then the corresponding ordinate of this line.

While at any time the curve of value may be taken as a straight line, the same straight line will not necessarily serve throughout the life of the property, especially if obsolescence is allowed as a cause of depreciation in estimating the cost of reproduction. Suppose, for example, that a new invention enables the property to be replaced by one costing half as much. The present value of the old property will then fall from the amount represented by MT, Fig. 1, to that represented by NT, the ordinate EO being the replacement cost (or cost of the new property) and T the time the new property was put on the market. The broken line $AMNB$ will then be the curve of value.

SCRAP VALUES. — The scrap value of a property is its residual value at the end of its useful life after deducting the expense of removal to a market and the expense of selling. If in Fig. 1 the line OP is taken to represent the useful life of the property, the ordinate BP represents the scrap value. Scrap value, therefore, not only depends upon the nature of the property, but also upon the location and the time of the sale. For example, a machine which might have a large scrap value in New York would possibly have a zero or negative scrap value at a mine in Nevada because the cost of removal to a market might cancel the profits from a sale. A property may depreciate to scrap value without deterioration, merely by the loss of valuable association or obsolescence. For example, a miner's stamp mill, in perfectly good condition, might become valueless because of the exhaustion of the mine, its distance from a market making its sale impracticable. It thus appears that data on scrap value should be carefully scrutinized before being adopted for any particular enterprise.

MAINTENANCE AND DEPRECIATION CHARGES AND DEPRECIATION FUND. — On account of deterioration, it is necessary to make replacements and repairs. Those replacements and repairs which occur frequently, or which severally cost a small proportion of the replacement cost of the whole property, should be paid for out of the annual earnings and thus charged to direct operating expenses. Such charges are called maintenance charges. Replacements, which occur infrequently and which cost an important proportion of the whole replacement cost, cannot be paid for out of the annual earnings without causing exaggerated operating charges in given years, unless a separate sum is set aside each year to provide in advance for the impending replacements. Such a sum is called a depreciation charge and the accumulated fund, made up of these annual sums, and the interest thereon, if invested, is called a depreciation fund or depreciation reserve. If the total annual replacements of a property do not fluctuate to such an extent as to affect the financial stability of the enterprise to which it belongs, it is not advisable to create a depreciation fund, while if they do affect the financial stability, a depreciation fund is necessary to avoid disaster.

Thus a large concern, owning property which requires replacements in small units, may dispense with a depreciation fund if care be taken to distribute replacements over several years. Another concern, having to face the replacement of a large proportion of its property, might be seriously embarrassed and would probably have to resort to one of the following expedients: (a) to borrow money on the strength of future earning capacity, such loans being gradually liquidated from the future earnings; (b) to issue stocks or bonds to purchase renewals of property that is already represented in capital, a pro-

cedure which is financially unsound and in many countries illegal; (c) to go into the hands of a receiver. Such a concern should obviously provide a depreciation fund. When the total replacements of a property fluctuate to such an extent that it is advisable to establish a depreciation fund to obtain financial stability, some criterion is desirable wherewith to judge which replacements should be charged to the maintenance account and which to the depreciation account. It is difficult to devise a rational criterion because so many unknown quantities enter into it. Hence it is usual to adopt an arbitrary rule, such as to charge to the depreciation fund the cost of entire renewals and to the maintenance account, partial renewals. Such a rule is obviously open to somewhat free interpretation. This practice is, however, far from being universal, some companies fixing an arbitrary limit, such as $500, and all renewals or repairs less than this are charged against maintenance and all greater than this against the depreciation fund. In several states the Public Service Commissions issue rules on this subject.

AMORTIZATION OR SINKING FUND. — When a property is purchased with borrowed capital, e.g., bonds, it is customary to set aside each year a sum which, with the accumulated interest, will pay off at some stated future time the debt thus incurred. The fund thus accumulated is called an amortization or sinking fund. The depreciation fund should be carefully distinguished from this amortization or sinking fund. The former exists solely for the purpose of equalizing operating expenses from year to year; the latter for the purpose of discharging the debts incurred in purchasing the property.

INVESTMENT OF DEPRECIATION FUND. — The question of what constitutes proper care of a depreciation fund is of considerable importance. Some maintain that such a fund should be invested only in securities with a regular market value and thus salable at any time. Another view is that this fund can be invested as well in the company's own business, provided it be kept in such a way as will render it readily available when needed. It may be urged against the first plan that the investment of these funds in such a manner that they can be turned into cash quickly involves either their deposit with a bank or trust company at a nominal rate of interest or their investment in low-interest-bearing securities. Thus, it appears inconsistent for the company to be borrowing money at high interest on the one hand and loaning it at low interest on the other hand, unless there is some excellent excuse for so doing.

As a matter of fact, what actually occurs in the finances of many companies is something like this: The earnings are sufficient to provide an amount for a depreciation fund. The need of increased capital to meet the growth of business is urgent. The amount which should rightly be put in a depreciation fund is actually invested in additional plant. Now, there does not appear to be a fundamental error about such a procedure, because, by investing this money in additional plant, the company has increased its assets by an amount which offsets the corresponding depreciation in value. The weakness of the plan is that it does not definitely provide money which can be used for replacement. Therefore, what occurs is that, after putting surplus net earnings into additional plant for a number of years, the company effects a reorganization of some kind and issues additional securities equal to the additional value which has been put into the property from year to year. Part of these securities are then used to rehabilitate the property. The effect of this plan is that the cash which is necessary for renewals is secured by the sale of securities at the time of reorganization, instead of by the deposit of the surplus as a depreciation reserve from year to year and the sale of new bonds or stock to pay for the additions to the plant. In the meantime the company has had the use of its own money.

The chance of friction through this plan, especially under commission regula-

tion of the issue of securities, lies in the possibility that the amounts spent out of the depreciation fund for enlarging the plant will not be recognized as an increase in assets against which additional securities may be issued when the company desires. The Massachusetts Gas and Electric Light Commission has decided that in order to keep a company's accounts properly it should pay for additions to plant by the sale of additional securities, rather than by taking the money out of net earnings. In cases where new securities are issued to pay for all increases in plant one course to pursue would be to invest the depreciation fund of the company in its own securities until such time as the cash may be needed for replacements caused by depreciation, when they should be taken from the company's treasury and sold. If such securities can be sold promptly enough or used as collateral for a loan to provide against any embarrassment, such a plan should be sound. Whatever plan is followed, either voluntarily by the companies or by direction of the commissions controlling them, it is equally important that the amount set aside for depreciation and the amount expended in new plant should be distinguishable in the accounts. (*Editorial Elec. W., 1912, Vol. 59, p. 126.*)

In the case of a property made up of a number of elements each having a different period of life, the disbursements from the depreciation fund after a certain number of years will, on the average, equal the accessions to this fund. The fund, however, should not be allowed to fall below an amount sufficient, without additional payments into it, to take care of the replacements for a reasonable period. Three years has been suggested as such a reasonable period, but this will depend largely upon the nature of the property.

ANNUAL DEPRECIATION AND ANNUAL DEPRECIATION CHARGE. — If the depreciation fund is invested, each annual payment draws interest from the time it is made, and, therefore, the annual payments necessary to make the fund equal to the difference between the replacement cost and the scrap value of a given property at the end of the life of the property, i.e., the depreciation charge, will be less than the annual depreciation, or decrease in value. Where the value of the property is assumed to decrease uniformly the depreciation charge is calculated as follows. Let A be the replacement cost of the property and B its scrap value at the end of n years. Then the annual depreciation is

$$D = \frac{A - B}{n} \text{ dollars.}$$

If the annual payments into the depreciation fund are made at the end of each year, and each payment draws compound interest at the rate of $100\,r$ per cent per annum, then the annual depreciation charge to give $A - B$ dollars at the end of n years is

$$D_c = (A - B)\frac{r}{(1 + r)^n - 1} \text{ dollars.}$$

If the annual payments into the depreciation fund are made at the beginning of each year the annual depreciation charge must be

$$D_c = (A - B)\frac{r}{(1 + r)^{n+1} - (1 + r)}.$$

The percentage depreciation, referred to the replacement cost, is $100\,p$ where

$$p = \frac{A - B}{nA} \text{ (a decimal fraction).}$$

The value of the property m years from the time of purchase is

$$V = A - \frac{m}{n}(A - B) \text{ dollars.}$$

Example. — A property costs $100 and its replacement value throughout its life of 8 years remains constant and equal to its first cost; the scrap value at the end of 8 years is $20, (1) what is the annual depreciation D, and (2) what must be the depreciation charge D_c to replace the property at the end of its life if invested at 4 per cent at the end of each year?

$$D = \frac{A - B}{n} = \frac{100 - 20}{8} = \$10. \qquad (1)$$

$$D_c = (100 - 20)\frac{.04}{(1.04)^8 - 1} = \$8.70. \qquad (2)$$

The following methods are also employed for determining the depreciation charge:

(1) **Depreciation Charge a Fixed Percentage of the Value at the Beginning of Each Year.** — The value of the property is assumed to decrease each year by a fixed percentage of its value at the beginning of that year, and the depreciation charge is taken equal to this decrease in value, no account being taken of interest on the annual payments into the depreciation fund. On these assumptions, using the same notation as in preceding paragraph, we have that the percentage annual decrease in value is 100 p where

$$p = 1 - \sqrt[n]{\frac{B}{A}} \text{ (a decimal fraction).}$$

The depreciation charge at the end of the mth year is then

$$D_c = pA\left(\frac{B}{A}\right)^{\frac{m-1}{n}} \text{ dollars}$$

and the value at the end of the mth year is

$$V = A\left(\frac{B}{A}\right)^{\frac{m}{n}} \text{ dollars.}$$

It is, therefore, evident that this scheme results in the annual appropriation of decreasing increments to the fund. This scheme is inapplicable to a property having a definite life and no scrap value. While it is strongly recommended by some engineers, others go to the opposite extreme of recommending a system which makes the depreciation charge grow as the years pass by.

(2) **Depreciation Charge a Fixed Percentage of Gross Earnings.** — The table on the following page, quoted from H. Floy, gives the practice of several companies.

(3) **Depreciation Charge a Fixed Percentage of Net Earnings.** — This scheme is financially unsound.

(4) **Depreciation Charge a Fixed Amount per Kilowatt-hour output,**

Name of company	Per cent of gross revenue expended or appropriated for	
	Maintenance	Depreciation
Milwaukee companies:		
Railway departments	11.3	9.9
Gas, electric-light and steam-heat departments	6.15	8.12
United Railways Company of St. Louis	13.67	10.0
Union Electric Light and Power Co., St. Louis	4.95	16.0
Suburban Electric Light and Power Company	7.10	10.85
Detroit Edison Company and subsidiaries	6.45	10.23
Omaha and Council Bluffs Street Railway Company	....	10.0
Chicago street railways	6.0	8.0

companies. According to H. Floy "the New York Edison Company charges off monthly for renewals and replacements, etc., an amount equal to one cent per kilowatt hour on current sold to general consumers in addition to wear and tear. In Cleveland, 5 cents per car mile is provided to cover both maintenance and other deterioration. In Brooklyn, the subsidiaries of the Brooklyn Rapid Transit System allow amounts varying from 2.7 cents to 4.4 cents per car mile for equipment of surface roads and from 1.4 cents to 2 cents per car mile for equipment of either elevated or partly elevated railways; from 2.2 cents to 2.4 cents per car mile for way and structures for surface roads; from 1.1 cents to 1.8 cents for elevated or partly elevated railways, to cover not only obsolescence, inadequacy, renewals and replacements but also repairs and maintenance."

LIFE OF PROPERTIES. — The expected life of electrical and other machinery and equipment, according to various authorities, is given in the following table. As many electrical machines, which are the first of their kind, are still in service, it is obvious that the lengths of life are really not known in many cases. Obsolescence and inadequacy have moreover been more responsible than deterioration for the replacement of electrical apparatus.

The New York First District Public Service Commission has assumed the life of electric lighting and gas properties as a whole to be about 20 years. The Wisconsin Commission has similarly decided that 18 years is a fair life for electric railway properties and 17½ years for electric lighting properties. (*L. R. Nash, Stone & Webster Journ., 1912.*)

Data on depreciation is usually given in terms of the life of the property or as a percentage depreciation. In the table below some authorities give the life only, some per cent depreciation only, and others both life and per cent depreciation. In all cases where life and per cent depreciation are both given by the same authority, the figures show that zero scrap value has been assumed; that is, the per cent depreciation p is taken equal to $\frac{100}{n}$ where n is the years of life. The following abbreviations are used:

A: Adopted by the Chicago Union Traction Co.
B: Milwaukee Electric Railway and Light Co.
C: J. W. Alvord.

D: Chicago city railways.

[W. A. Del Mar.]

DERIVATIVES. — (*See also Equations, Differential; Integrals; Maxima and Minima; Series, Mathematical*).

Differentials. — Let y be a function of x, i.e., a quantity which varies continuously with variations of x. If x be increased or decreased by the smallest amount conceivable, y will change by a correspondingly small amount. Such small variations are called "differentials," and are symbolized thus: dy and dx, where d is not a quantity but a symbol meaning "the smallest conceivable value of" y or x.

Derivative or Differential Coefficient. — The ratio $\frac{dy}{dx}$ is the rate of change of y with regard to x and is called the "derivative" or "differential coefficient" of y with respect to x.

Geometrical Meaning of a Derivative. — If a curve be plotted between x and y for any equation $y=f(x)$, and a tangent drawn to the curve at any point, Fig. 1, then the tangent of the angle θ between this tangent and the axis of x is equal to $\frac{dy}{dx}$.

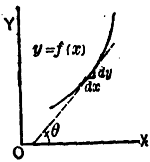

Fig. 1

Differentiation. — Differentiation is the process of obtaining the derivative of a function. If $y=f(x)$

$$\frac{dy}{dx}=\frac{df(x)}{dx}$$
$$=\frac{f(x+dx)-f(x)}{dx}.$$

Example. — If

$$y=ax^2$$
$$\frac{dy}{dx}=\frac{a(x+dx)^2-ax^2}{dx}$$
$$=\frac{a\,dx\,(2x+dx)}{dx}$$
$$=a\,(2x+dx).$$

As dx is the smallest conceivable value of x, it is so small compared to x that it may, with the smallest conceivable error, be neglected. Hence,

$$\frac{dy}{dx}=2ax.$$

Formulas for Differentiation. — (u, v, x and z are variables; a is a constant.)

$$\frac{d}{dx}(u+v)=\frac{du}{dx}+\frac{dv}{dx}$$

$$\frac{d}{dx}(au)=a\frac{du}{dx}$$

$$\frac{d}{dx}(uv)=v\frac{du}{dx}+u\frac{dv}{dx}$$

$$\frac{d}{dx}\left(\frac{u}{v}\right)=\frac{v\frac{du}{dx}-u\frac{dv}{dx}}{v^2}.$$

When x is itself a function of some other variable z,

$$\frac{du}{dx} = \frac{du}{dz} \cdot \frac{dz}{dx}.$$

TABLE OF DERIVATIVES

Function $f(x)$	Derivative $\frac{d}{dx}f(x)$	Function $f(x)$	Derivative $\frac{d}{dx}f(x)$
x^n	nx^{n-1}	$\tan^{-1} ax$	$\frac{a}{1+(ax)^2}$
$\sin ax$	$a \cos ax$	$\sinh^{-1} ax$	$\frac{a}{\sqrt{1+(ax)^2}}$
$\cos ax$	$-a \sin ax$	$\cosh^{-1} ax$	$\frac{a}{\sqrt{(ax)^2-1}}$
$\tan ax$	$\frac{a}{\cos^2 ax}$	$\tanh^{-1} ax$	$\frac{a}{1-(ax)^2}$
$\sinh ax$	$a \cosh ax$	$\log_a x$	$\frac{1}{x}\log_a \epsilon$
$\cosh ax$	$a \sinh ax$	$\log_\epsilon x$	$\frac{1}{x}$
$\tanh ax$	$\frac{a}{\cosh^2 ax}$	$\log_{10} x$	$\frac{0.4342944819}{x}$
$\sin^{-1} ax$	$\frac{a}{\sqrt{1-(ax)^2}}$	a^x	$a^x \log_\epsilon a$
$\cos^{-1} ax$	$-\frac{a}{\sqrt{1-(ax)^2}}$	ϵ^x	ϵ^x

Note: See also Table of Integrals in article on *Integrals* noting that the column there headed "Function" is the derivative of the column headed "Integral."

Second Derivative. — The derivative of a derivative, i.e., $\frac{d}{dx}\left(\frac{dy}{dx}\right)$, is usually written $\frac{d^2y}{dx^2}$. Similarly $\frac{d}{dx}\left(\frac{d^2y}{dx^2}\right)$ is called the third derivative and is written $\frac{d^3y}{dx^3}$, and so on.

[W. A. Del Mar.]

DETECTORS, ELECTRIC WAVE. — (*See also Waves, Electromagnetic; Wireless Telegraphy; Wireless Telephony.*) Electric-wave detectors are devices for rendering audible or visible the effects of extremely minute oscillatory electric currents. The detector is usually employed in connection with some auxiliary indicating instrument, such as a sensitive relay, a telephone receiver or a galvanometer.

APPLICATIONS. — The principal application of wave detectors is to wireless telegraphy, either in the actual receipt of messages or in measurements of oscillatory currents of high frequency. However, the thermal detectors, the crystal detectors, the electrolytic detectors and the vacuum detectors are also applicable to the measurement of small alternating currents of commercial frequency. The crystal detectors and also Duddell's thermogalvanometer have been used in measurement of the small alternating currents generated in a magneto telephone by sound waves and have thus served as instruments for the measurement of the distribution of sound in an auditorium.

TYPES OF DETECTORS. — The more important detectors, together with their associated indicating instruments, are briefly described and classified in the following paragraphs. Six different types of detectors are in use; namely, coherers, magnetic detectors, thermal detectors, electrolytic detectors, crystal rectifiers and vacuum detectors.

Sensitiveness of the Various Types. — Coherers are too insensitive to be used except for very short distances. They are so troublesome to adjust that, except where it is required to trip a relay for setting machinery in motion or for operating a call, they cannot compete with the electrolytic, magnetic, crystal or vacuum detectors. The electrolytic detector, which has perhaps not been excelled in sensitiveness, is, however, somewhat more troublesome than some of the others. The crystal detectors are the easiest to construct, maintain and operate. Of these galena, iron pyrite, molybdenite, silicon, and the perikon combination are nearly equal in sensitiveness if made of carefully selected specimens.

Coherers. — Under this title will be included those detectors which employ one or more loose contacts between conducting bodies, and which require to be shaken or moved to restore the contact to its sensitive condition after the receipt of a signal. Under normal conditions the resistance of such a device is high, but upon the receipt of the electric waves, the resistance is lowered. The manner in which this is accomplished is not certain. Some writers have believed that the separating film was removed by the heat effect of the oscillations; others have looked to the electrostatic attraction for a force to draw the particles nearer together and diminish the resistance of the film. It seems to the writer not improbable that the action of the oscillations, apart from the heat action or electrostatic attraction, may produce immediately a motion of electrons into the region of separation between the filings, and that these electrons serve as carriers of the oscillatory currents and of the local battery current.

Branly-Marconi Coherer (Figs. 1 and 2). — The Branly coherer, in the highly improved form devised by Marconi, consists of an insulating tube (Fig. 1) containing metallic filings (preferably 96 per cent nickel and 4 per cent silver) between two plugs *PP* of silver slightly amalgamated. To prevent deterioration by the action of atmospheric gases, the tube, which is usually of glass, is exhausted and sealed up. The plugs should fit accurately within the glass tube and should be within $\frac{1}{50}$ inch of each other. The filings in this space, for high

Fig. 1. Coherer

silver, and should be of uniform size, between 80 and 100 mesh. They should be dry and free from grease and dirt. In sealing up the containing tube after exhaustion, care should be taken not to heat the filings. In order that the coherer may not be injured, not more than $\frac{1}{1000}$ ampere should ever be sent through it.

Fig. 2 shows a coherer *Co* of this form in series with an antenna and ground. Under the action of the electric waves, the resistance of the coherer falls to a small value, and a current flows from the battery B_1 through the coherer and through the field coils of a relay *R*. The core of the relay is thus magnetized and attracts its armature so as to close the gap *A*. The closing of this gap, which is in a local circuit containing a battery *B*, a trembler *T* and a sounder *S*, causes the armature of the sounder to strike downward and at the same time starts the trembler *T* into activity. So long as the electric oscillations in the antenna circuit are kept up by the incident electric waves the coherer is repeatedly cohered and decohered and the sounder armature, which possesses considerable inertia, is held down. As soon, however, as the arrival of the waves ceases, the coherer, under the action of the trembler, is restored to its high resistance and the sounder armature flies up. The length of the time that the armature is down is determined by the length of the signal and enables the receiving operator to distinguish dots from dashes. The sounder may be replaced by a Morse tape recorder, so that the signals may be recorded. The zigzag dotted lines *P*, P_1, *q*, *q′* and *h* of Fig. 2 indicate resistances shunted about each electromagnet and each contact point of the local circuits, for the purpose of preventing rise of potential due to the back kick of the several inductances of the local circuits. Such a rise of potential, if not prevented, would operate to cause a coherence of the detector at the time when a decoherence is required.

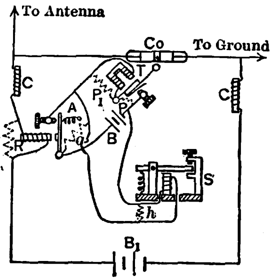

Fig. 2. Coherer Connections

The relay used with the coherer should be a highly sensitive polarized relay of several thousand ohms resistance. The magnet of the trembler and that of the sounder should be wound to equal resistance with each other, and the protective resistances should be of about the same resistance as the coils about which they are placed.

Lodge-Muirhead-Robinson Coherer (Fig. 3). — Another form of coherer, due to Lodge, Muirhead and Robinson and shown in Fig. 3, consists of a steel wheel *A*, rotated by clockwork, in contact with a film of oil on the surface of mercury. A binding post connected to a brush *E*, making contact with the axle of the wheel, is one terminal of the instrument, and a second binding post *H* connected with the mercury is the other terminal. If connected by these terminals to an antenna and ground, the oily contact between the steel disk and the mercury changes resistance under the action of electric oscillations, and this changing resistance is evidenced by a siphon recorder shunted through a battery to the terminals of the detector.

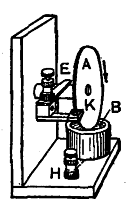

Fig. 3. Lodge-Muirhead Coherer

The Magnetic Detector (Fig. 4). — Of this form of detector the most prominent representative is the continuous magnetic band detector of Marconi.

This instrument, shown in Fig. 4, contains a belt of fine iron wires, insulated from one another, and carried over two wheels *DD*, one of which is slowly driven by a motor. This belt of iron wires passes through a transformer consisting of a primary coil *bb* surrounded by a secondary *C*. Placed near the transformer is a pair of permanent magnets *SNNS* arranged to induce consequent poles in the moving belt of iron. The primary coil *bb* of the transformer is connected in the oscillating circuit *AE*, while the secondary coil *C* of the transformer is connected to a sensitive telephone receiver *R*. Each train of electric oscillations through *bb* modifies the magnetic state of the magnetized band, by suppressing hysteresis, and thereby induces a current in the telephone. A series of trains of waves arriving in uniform sequence gives a uniform sequence of pulls to the diaphragm and results in a musical note. The note continues as long as the transmitting key is pressed and constitutes a long or short note according as a dash or dot is made at the transmitting station. The pitch of the note is the pitch of the spark at the sending station.

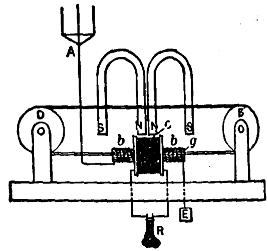

Fig. 4. Magnetic Detector

Thermal Detectors. — Two types of thermal detectors — used chiefly for measuring purposes — have been employed as detectors of electric oscillations. One of these types, of which the "bolometer" of Paalzow and Rubens and the "barretter" of Fessenden are examples, employs the heat-effect of the oscillations to change the resistance of a fine wire; the other type, exemplified in Klemencic's "thermal junction" and Duddell's "thermogalvanometer," employs the heat effect concentrated at a thermal junction to produce thermoelectromotive force at the junction.

Barretter (Fig. 5). — The barretter consists of a very fine platinum wire enclosed in a glass tube. This wire is connected in series with the antenna and is shunted by a local circuit containing a battery and telephone. The change in the resistance of the wire due to the heating effect of the oscillations passing through it to ground causes a variation of the current in the local circuit and thereby produces a click in the telephone. The platinum wire is obtained by dissolving off the silver from a short length of Wollaston wire.

Fig. 5. Barretter

Thermogalvanometer (Fig. 6). — The essential parts of Duddell's thermogalvanometer are shown in Fig. 6. A thermal junction *SbBi* forms a part of a loop *L* of wire suspended between the poles of a magnet *NS*. A stationary heater of fine platinum wire is placed near the thermal junction, and this heater is traversed by the oscillatory currents to be measured. Heat developed in the heater is radiated or convected to the thermal junction and produces a thermoelectromotive force at the junction. This causes a small unidirectional current to flow in the loop, which is, in consequence, deflected by the magnetic field. The deflections are read by the mirror *M* with the aid of a telescope and scale.

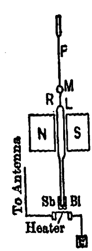

Fig. 6. Thermogalvanometer

Electrolytic Detector (Figs. 7–9). — This detector in its best form, as described by Fessenden and shortly afterwards by Schloemilch, consists of a fine platinum wire dipping into electrolyte contained in a small vessel, so that the fine wire just touches

the electrolyte. The fine wire is attached to one of the terminals. As a second terminal a larger wire entering the electrolyte or a metallic cup containing the electrolyte serves. The fine wire is adjustable as to depth in the liquid or else the fine wire is sealed into a glass tube so that only a very minute portion of the end of the wire protrudes, and this glass tube containing the sealed-in

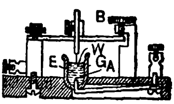

Fig. 7. Electrolytic Detector

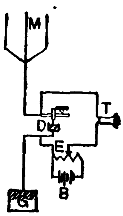

Fig. 8. Circuit with Electrolytic Detector

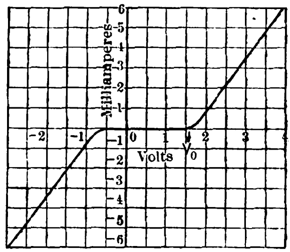

Fig. 9. Current-voltage Curve of Electrolytic Detector

wire is dipped into the liquid. As electrolyte 20-per-cent nitric acid is about the most sensitive liquid, but salt solution, sulphuric acid or any good conducting electrolyte may be used. Fig. 8 shows an electrolytic detector *D* in a position to be traversed by electric oscillations in the circuit *MG*. As indicating instrument a telephone receiver in series with a source of e.m.f. is shunted with the detector.

Theory of Electrolytic Detector. — The electrolytic detector, when used with a polarizing voltage of about 1.6 volts (i.e., when a direct-current voltage of this value is impressed across the terminals of the detector), is a rectifier for alternating electric currents, and this fact accounts for its action as a detector for electric oscillations. Fig. 9 shows a characteristic curve obtained by plotting the direct current through an electrolytic detector against the direct-current voltage applied to produce the current. The curve of the upper quadrant is obtained with the applied voltage in one direction, while the curve of the lower quadrant is obtained with the voltage in the opposite direction. Suppose this polarizing voltage to be V_0 (about 1.6 volts). It is seen from the curve that a steady current of about 0.15 milliampere will flow through the detector. Now let us suppose that an alternating e.m.f. of amplitude 0.5 volt be superposed upon the polarizing voltage. When the alternating voltage is in the direction of the polarizing voltage, we have a total voltage of 2.1 volts and a current of 1.2 milliamperes (from the curve). When the alternating e.m.f. is reversed, the total impressed voltage is 1.1, with a resultant current practically equal to zero (from the curve). Hence the polarized electrolytic cell acts as a rectifier of the oscillations passing through it to ground. The manner in which such a rectifier causes the oscillations to affect the telephone is the same as the action of the crystal rectifiers described below.

Design of Electrolytic Detector. — The fine platinum wire should be 0.0001 or 0.0002 inch. It may be bought as Wollaston wire — platinum core with an exterior of silver — from dealers in platinum. The silver may be removed, after attaching a length of ½ to ¼ inch of the Wollaston wire to a larger wire for support, by dipping the wire a short way into the electrolyte *E* of 20 per cent nitric acid (Fig. 7) and connecting the detector in series with the

receiving telephone and the adjustable source of voltage (potentiometer) that is to be employed as the polarizing voltage in the actual use of the detector. In this connection for clearing off the silver, the fine wire should be anode, and the action may be hastened by raising the polarizing voltage until bubbles begin to escape causing a hissing sound in the telephone. After the silver is removed, the polarizing voltage should be reduced to the value at which the hissing noise just begins; this is the most sensitive adjustment for receiving messages. As a suitable polarizing voltage with the electrolytic detector (platinum point anode), a potentiometer resistance of about 500 ohms should be connected in series with three dry cells, and the polarizing voltage taken as a drop off of this potentiometer wire. The receiving telephones (of the head type) should have a resistance of 2000 or more ohms for both ear-pieces. The resistance of 500 ohms will be sufficient to protect the cells from too rapid use and will not be enough to introduce derogatory resistance in the telephone circuit, as the detector has a high resistance and is also in series with the telephone.

Crystal Rectifiers (Figs. 10–12). — The detectors of this class make use of the high-resistance contact between a crystalline conductor and a metallic electrode or between two crystalline bodies. The parts are all solid. A great

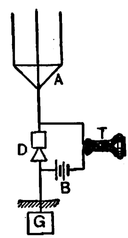

Fig. 10. Crystal Detector Connections

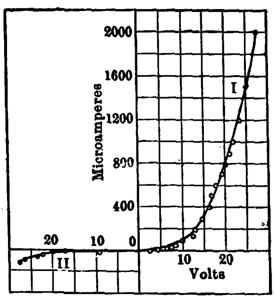

Fig. 11. Current-voltage Curve for Carborundum Detector

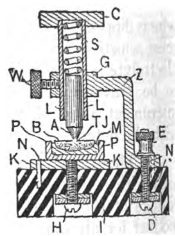

Fig. 12. Mounting of Silicon Detector

variety of substances have been used in detectors of this type; for example, carbon, carborundum, tellurium, silicon, anastase, brookite, octahedrite, molybdenite, chalcopyrite, zincite, iron pyrite, bornite, galena and many others. The contact of any of these substances against a metallic conductor serves as a detector for electric oscillations. Also in some cases the substances enumerated may be used in pairs, one against another, with improvement in the sensitiveness or constancy of action.

Fig. 10 shows diagrammatically the connection of the crystal contact detector into a simple oscillating circuit AG. A telephone T or galvanometer is used as indicating instrument. Some of the detectors are more sensitive when used with a local e.m.f. B in the telephone circuit, while some others are more sensitive without the local battery.

Theory of Crystal Rectifiers. — The detectors making use of a contact with a crystalline substance are all unilaterally conductive; that is to say, they permit the passage of a greater current in one direction than in the opposite direction under the same applied voltage. In addition, these detectors all have a rising current-voltage characteristic. Fig. 11 shows a current-voltage curve for one of these detectors. This curve is taken from experiments on the con-

tact of a brass rod against a carborundum crystal. Although the carborundum detector is not as sensitive as some of the other crystal detectors, this curve, except for magnitudes, is typical of all the crystal detectors.

The fact that the current in Fig. 11 is greater in one direction than in the other under the action of the same impressed voltage makes the detector a rectifier of alternating currents, without an auxiliary battery. Also the fact that the detector has a rising current-voltage characteristic makes it a rectifier when used with an auxiliary battery, as may be shown by a discussion similar to that employed in explaining the action of the electrolytic detector. Whether the detector is a better rectifier with or without the auxiliary battery depends upon the shape of the current-voltage curve.

The action of a rectifier in causing the motion of the telephone diaphragm when oscillations pass through the rectifier is as follows: Let us take the case of the simple form of receiving circuit shown in Fig. 10, with or without a battery in the telephone circuit.

A train of incoming waves produces an alternating e.m.f. in the antenna circuit. This e.m.f., when in one direction, produces a large current through the detector *D* charging the antenna. When the e.m.f. reverses, the current from the antenna to the ground through the detector is smaller, thus leaving the antenna charged with a small quantity of electricity. The effect of the whole train of waves is additive, so that this charge on the antenna is cumulative. The accumulated charge on the antenna escapes through the telephone shunted about the detector, causing the diaphragm to move. Each subsequent train of waves causes a similar motion of the diaphragm, which is evidenced as a note in the telephone with the train frequency of the waves.

It is immaterial whether the detector permits the larger current to flow upward, charging the antenna positive, or permits the larger current in the downward direction, charging the antenna negative. The explanation is the same in both cases.

With very slight change this explanation can be made to apply also to those cases in which the detector is in a condenser circuit coupled inductively or directly with the antenna circuit.*

Design of Crystal Rectifiers. — A typical form of construction of the crystal detectors, which, however, may be greatly varied, is shown in the mounting of Mr. Pickard's silicon detector (Fig. 12).

A rod of brass *A* is pressed down by a spring *S* into contact with a mass of polished silicon *B*, embedded in an easily fusible solder of Wood's metal *M*. The solder in which the silicon is embedded is contained in a metallic cup *P*, which rests upon a metallic plate *K*. Connection to the rod *A* is made by means of the binding post *E*. Connection to the silicon is made by means of a binding post not shown, which connects with the plate *K*. The ability to move the cup containing the embedded silicon is an advantage, because not all parts of the surface of the silicon or other crystalline material of the detector are equally sensitive, and this motion permits the selection of a sensitive place on the material, as the point of contact. Mr. Pickard sometimes uses two of these active materials in the same detector. For example, a contact of zincite with bornite (each held in a bed of Wood's metal) is a highly sensitive electric wave detector.

In the zincite-bornite detector, sold under the trade name of perikon, the crystalline bodies are not polished, but are used as rough fragments.

Another form of highly sensitive detector makes use of galena as a sensitive material. By selection from the galena of various localities, specimens may be

* Quoted from Pierce's "Principles of Wireless Telegraphy," McGraw-Hill, N.Y., 1910.

found that are highly sensitive when used with a very fine copper wire (No. 36 or No. 40 B. & S.) as contacting element. In this case no spring is required, as the stiffness of the fine wire is about sufficient to give the required pressure. Arrangement should, however, be made for displacing the galena so as to make the contact at a sensitive point.

For ruggedness as a detector of electric waves, though rather insensitive, a crystal of carborundum with a metallic rod in contact under a considerable pressure is recommended. Also selected specimens of molybdenite with a metallic contact may be rugged and highly sensitive. Molybdenite is however a soft material and is likely to be injured by unskillful adjustment.

Vacuum Detectors (Figs. 13 and 14). — The wave valve of Fleming and the audion of DeForest make use of the rectifying property of a vacuous space containing electrons produced by an incandescent filament. In Fleming's valve, Fig. 13, a bulb pumped to a high degree of exhaustion contains a filament *b* of carbon, tungsten or tantalum, like that of a low-voltage incandescent lamp.

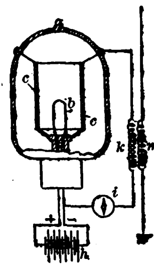

Fig. 13. Fleming's Valve

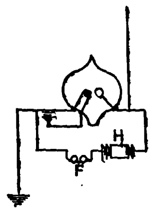

Fig. 14. DeForest's Audion

This filament is heated to incandescence by the current from a local battery *h*. The hot filament serves as one terminal of the detector. The other terminal is in the form of a metallic cylinder *c* surrounding the filament. These two terminals in the circuit shown in the figure are connected with a coil *k* and a galvanometer *i*. The electric oscillations in the antenna circuit, flowing through the coil *m* in the antenna circuit, act inductively on the coil *k* in the detector circuit, giving an alternating e.m.f. at the terminals of the detector. The vacuum valve permits the flow of current in only one direction, so that the alternating e.m.f. produces a direct current through the detector and galvanometer.

DeForest's arrangement, shown in Fig. 12, is a modification permitting the use of a telephone receiver *F* as indicating instrument. For greater sensitiveness a battery *H* is used in the local circuit with the telephone receiver.

[G. W. Pierce.]

DISPATCHING OF TRAINS BY TELEPHONE. — (*See also articles on Telephony.*) Up to 1907 train dispatching was done almost entirely by the telegraph. In that year the telephone began to replace the telegraph for this purpose. At the beginning of 1912, about 60 railroads in the United States, operating over 30,000 miles of line, had abandoned telegraphic train dispatching in favor of the telephonic method.

Telephone train dispatching has many advantages over the former method. The dispatcher's work consists in the main of gathering information and issuing orders for train movements. These operations are much quicker by the use of the telephone and are no less accurate. Special training in the use of the apparatus is not as necessary as when telegraphy is employed. All the agencies are brought into closer personal relations, with the result that there is better co-operation and better discipline. The dispatcher can call and speak at the same time, which is impossible by telegraph.

It now is possible to operate dispatching lines as long and with as many stations as railway conditions may permit. The length of line and number of stations are not limited by the nature of the electrical equipment. Lines of 300 miles length are in operation, and 65 stations on one line are in successful use. More than 65 stations could be operated successfully if desired.

Dispatching circuits are multi-station lines, like the telegraph-dispatching lines they displace. Broadly speaking, they are selective party lines, but are equipped with systems of apparatus which allow the placing of many more stations on a line than is possible with any other party-line system so far developed.

Several train-dispatching systems are on the market, the principal ones being known as the Gill System, the Western Electric System, the Cummings-Wray System, and the Kellogg System. These are in general similar in that the dispatcher has means of calling any station selectively. In some systems he can call several stations at once by setting keys for them in advance and operating a common calling key.

Each way station is equipped with a device called a selector. These selectors can be operated only by the dispatcher. They work on the step-by-step principle and the whole object of the device is to close a contact at the station called and thus to ring a bell. No provision is made for cutting the way-station telephone set on and off the line, as secrecy is not aimed at. Any way station may communicate with the dispatcher at will by lifting the telephone receiver. The dispatcher wears a head telephone constantly and so listens upon the line at all times.

Train orders are written as given and received and are read back to the dispatcher by each station, the dispatcher underscoring each word once for each correct repetition from a way station.

[S. G. McMEEN.]

DISTRIBUTION LINES. — (*See also Conduits and Conduit Lines; Distribution and Transmission Systems; Transmission Lines; Wires and Cables; Wiring of Buildings.*) Two types of construction are employed, overhead and underground. Overhead construction has the following advantages (1) lower first cost, (2) easier to repair, (3) easier to change, (4) adaptability to higher voltages; while underground construction has the advantages (5) less unsightly, (6) less dangerous to the public, (7) less subject to damage by external agencies. The majority of circuits in use are overhead. Underground circuits are principally used in the central portions of the larger cities. When underground circuits are used a large part of the construction consists of a composite of underground and overhead construction.

MATERIALS FOR LINE CONSTRUCTION. — The principal elements for wood-pole construction are the conducting wires, insulation on the wires, insulators, tie wires, pins, cross arms, cross-arm braces, bolts, poles, guy wires, guy anchors. For underground construction, see *Wires and Cables, Insulated,* and *Conduits and Conduit Lines.*

Wires for Overhead Construction.— The conducting wires are usually of copper, sometimes of aluminum. Iron is not used as it costs more than copper for equal conductivity. Aluminum is used to a much less extent than copper; see articles on *Aluminum* and on *Copper*. Soft-drawn copper is usually employed for ordinary distribution work, as it has the greatest conductivity and is the easiest to work with. Medium-hard-drawn and hard-drawn wires are used in lines where great mechanical strength is necessary.

For overhead city distribution copper wires ranging in size from No. 6 B. & S. (or A. W. G.) to 500,000 circular mils are used; see *Wires and Cables*. Sizes larger than No. 0000 B. & S. are usually stranded. Conductors as small as No. 14 B. & S. have been used for overhead work but are too small as they are frequently broken by wind and sleet.

Standard Sizes of Wire. — Of the gage numbers between No. 6 B. & S. and 500,000 circular mils (*see Gages, Wire*), some are but little used because (1) the difference between consecutive sizes is less than is found necessary in usual practice and (2) the difference is too small to be readily detected by the ordinary lineman or stock keeper. In practice the number of sizes to be used and carried in stock has usually been reduced by omitting certain sizes; No. 5, 3 and 1 are nearly always omitted; practice regarding the omission of larger sizes varies. The most commonly used are No. 6, 4, 2, 0, 0000 B. & S. and 500,000 circular mils.

Wires for Underground Lines. — See *Wires and Cables, Insulated.*

Insulation on Overhead Wires. — Overhead conductors for city distribution are insulated with weatherproof braid. Two thicknesses are recognized, "double braid" and "triple braid," according to the number of coverings, though the actual thicknesses are not the same for different makes. Double braid is considered suitable insulation for use on voltages of 600 or less, and triple braid for voltages up to 2500 constant potential and on series-arc circuits of all voltages. To prevent the possibility of double-braid wire being used for voltages over 600 and to reduce the number of kinds of wire used, it is good practice to have all No. 0000 wires and smaller covered with triple braid. Ordinarily cables larger than No. 0000 are not used on voltages above 600 and may therefore be double braided.

Object of Insulation on Overhead Wires. — The insulation on overhead conductors is solely for the purpose of limiting the short-circuit current due to an accidental cross or grounding. The normal insulation of the line is

maintained by the insulators alone (*see below*); any reinforcement obtained from the insulation on the conductors is neglected in practice. While weatherproof braid is an imperfect insulator, it serves to eliminate the greater proportion of the short-circuits and arcs which would occur, due to momentary contact, were bare wires used. Rubber and other more perfect insulators are not used because of expense and the impossibility of maintaining perfect insulation, due to weakness, against mechanical injury and deterioration.

Bare wire is usually used on circuits operating at 10,000 volts and over to avoid giving a false sense of security. For voltages between 2500 and 10,000 insulated wire is often used, though the protection afforded is doubtful.

Extra Cost and Weight due to Weatherproof Braids.— In estimating the cost of a distribution line, the additional weight and cost of the weatherproof braids should be taken into account. The following is a rough comparison of bare, double-braided and triple-braided copper wire, the cost being based on copper at 15 cents per pound.

COMPARISON OF BARE AND WEATHERPROOF COPPER WIRES

Conductor	Relative weights			Relative Costs		
	Bare	Double braid	Triple Braid	Bare	Double Braid	Triple Braid
No. 6 B. & S., solid	100	123	137	100	127	141
500,000 cir. mil cable	100	112	117	100	115	121

The cost and weight of weatherproof insulation for aluminum wires are greater than for copper of the same conductance on account of the larger cross-section of conductor required.

Insulators for Overhead Lines. — City distribution circuits are ordinarily carried on double-petticoat deep-groove glass (D.P.D.G.) insulators; see article on *Insulators for Overhead Lines*.

Tie Wire. — The conductor is attached to the insulator by a tie wire of the same material as the conductor, though soft wire is usually employed even for hard-drawn conductors; the tie wire is either bare or insulated to correspond to the conductor. The size of tie wire is often the same as that of the conductor; for small wires it is merely a piece of conductor. With large conductors it may be as much as three sizes smaller. See also the section on *Installation* in the article on *Wires and Cables, Bare*.

Pins. — See article on *Insulator Pins*.

Cross Arms. — See article on *Cross Arms*.

Poles. — See article on *Poles for Overhead Lines*.

DESIGN OF CITY DISTRIBUTION LINES. — City distributing systems should be designed so that service may be given to any building in the city and ultimately to every building present and future. On certain streets pole lines may be omitted without defeating this object. The arrangement of lines which will serve scattered customers with the least number of poles will usually contain many poles which should not be used if the ultimate arrange-

ment were immediately constructed. Preliminary studies and designs should be made, first, of arrangements suitable for servicing the initial expected customers, second, of arrangements for ultimately servicing customers on every lot in the city, third, of a plan of extension by which the initial arrangement can be extended to the ultimate with the minimum expense in changing lines and services.

The Pole Line. — The pole lines perform two functions: (1) of carrying feeders from the station to the mains and (2) of carrying the mains supplying services to buildings immediately adjacent. In the old cities of the eastern part of the United States where the streets are crooked general rules for systematic line work cannot be followed far. In the newer cities of the West and South the streets are laid out at regular intervals and at right angles, dividing the city into rectangular blocks of equal size. In such cases the following rules should be followed:

(1) A pole line should continue on the same side of the street throughout its entire length and disconnected lines built in the same street should be on the same side, so that they may be connected when desired without crossing the street.

(2) The spacing between poles should be an exact divisor of the length of a block (including cross street), giving a uniform number of poles per block.

(3) Whenever the line crosses a street where there is, or may be, an intersecting line there should be a corner pole on the proper side of the intersecting street for making a junction.

These rules logically lead to the use of corresponding sides of all parallel streets.

When each block contains lots fronting on all four surrounding streets the servicing of every lot in the city would require poles on all streets, though on the streets in at least one direction the lines may be discontinuous. Often the lots all front on the streets in one direction, which are laid out to be principal streets, in which case no service lines are necessary in cross streets, though at intervals connecting lines are necessary.

Trunk Lines. — Where the location of power house or substation is fixed, trunk lines must be laid out from such point, but often a study of possible trunk-line arrangements made before the location of the power house is fixed will show that other locations are more advantageous. If distributing station (power house or substation) is centrally located, there should be at least four main trunk lines (of poles) from it, say north, east, south and west. A short distance from the station they should be divided into branches, then subdivided into smaller branches and finally merge into the service lines. The trunk lines should be laid out: (1) on back streets where the large poles, numerous and heavy wires and heavy guying will not be conspicuous, (2) on side streets or streets little built up so that interruption to service due to fire in adjacent buildings will be infrequent, (3) on streets where there are few trees, (4) on streets where there are no jogs or offsets to weaken the line and require heavy guys, (5) on streets which lead directly to the section supplied, penetrate its center and intersect the maximum number of service lines. Even when the station location is excellently chosen these desirable conditions will have to be compromised to a serious degree.

Street and Alley Service Lines. —With the symmetrical arrangement of lots described above there is often an alley through each block parallel with the principal streets. Under these conditions there is therefore a choice of two methods of laying out the lines: (1) run the lines on the principal streets servicing the houses from the front and (2) run the lines in the alleys servicing

the houses from the rear. The disadvantages of the first are unsightliness of the poles and wires, difficulty of avoiding or of trimming shade trees; the disadvantages of the second are discontinuity of alleys, proximity of buildings (inflammable barns and out buildings in residence districts and of windows and fire escapes in business districts) and lack of established grade.

Composite Distribution. — The most expensive and difficult part of an underground system is that for taking the current from the conduit to the customer's building. This includes underground secondary mains, transformers, handholes, service pipes and wires. Where it is necessary to remove poles from streets but not to remove overhead wires from private property the pole lines are replaced by conduits which contain primary feeders and mains only. From the conduit in the street a small branch runs into the interior of each block where the ducts (usually iron pipes) come to the surface at the foot of a terminal pole up which the cables run. At the top the cables connect to overhead wires. The interior of each block contains a complete overhead distribution system of poles, transformers, secondary mains and services. Sometimes the servicing is done from a single centrally located pole and at others there may be a pole line of several spans length running longitudinally through the block. The most serious disadvantage of this method is that the poles and wires frequently have to be on private property, where no permanent rights may be obtained. Being dependent on concessions from one or more customers, the company does not have the independent position that a public service company should in order to serve all equally and fairly. The poles and circuits are therefore often put up of insufficient size without proper guying.

The composite system has the advantage of the overhead system in less unsightliness, less accessibility of public to high-voltage wires and less trouble from trees. In thickly built-up blocks its use results in a tangle of wires over roofs and along walls which may be as dangerous in case of fires or high winds as an overhead system. The composite system is used (1) in small cities where the load density is small and (2) in large cities in an annular district between overhead and underground construction; in either case it is usually an intermediate step from overhead to underground construction.

Crossing of Waterways; Submarine Cables. — Where a distributing system is divided by a navigable waterway the connection is usually made by submarine cables laid on the surface of the bottom, or better, below the surface in trenches dredged for the purpose. Cables may be single or multiple conductors, the latter being usually used for alternating currents to avoid reactance due to wire armor of cable. Two conductor cables may conveniently be of concentric type to give a true circular exterior. In laying cables it is desirable to keep them approximately parallel. Where one crosses under another it may be impossible to remove it. Each cable should be in a single length without joints, and the length should be made as short as possible, as repairs are very difficult and often impossible. At ends unimportant cables may be brought up a pole and connected to overhead wires; important cables should land in a cable house with suitable provision for disconnecting the cable or for transferring the overhead circuit to a spare cable in case of trouble, and also with lightning arresters. Submarine cables are weak links in a distribution system and may sometimes be avoided by crossing channels at sufficient height to clear the masts of ships.

Calculation of Size of Wires. — The size to be used depends upon the voltage drop which should be permitted, considering the probable growth of the load. The following table of per cent voltage drop in the various lines is representative of ordinary practice.

	For light
	Per cent
House wiring	2
Service wires	2
Secondary mains	5
Transformers	2
Primary mains	5
Primary feeders	10

The drop in the feeders is usually compensated for by raising the voltage at the substation or power station or by using voltage regulators; see *Distribution and Transmission Systems.*

Formulas for calculating the size of wire for a given length of line, given load and given distribution of load are given in the articles on *Transmission Lines* and *Wiring of Buildings.* Due to the uncertainty regarding the probable increase of load, a close calculation of the size of wire is seldom made, the engineer relying largely on his experience and judgment, making only a rough calculation as a check. For overhead lines 500,000 circular mils is usually the largest size used on account of the difficulty of supporting a larger wire; greater conductance is obtained by installing parallel circuits. For underground lines No. 0000 B. & S. three-conductor cable is the largest size that can be conveniently drawn into the ducts; 1,000,000 c.m. is the usual maximum size of single-conductor cable used.

Effect of Diversity Factor. — It should be noted that in a distribution circuit the maximum load on a feeder is less than the sum of the maximum loads on the mains which it feeds, these in turn are less than the sum of the maximum loads on the transformers connected to these mains, and so on. Therefore, whenever a circuit divides or subdivides, the aggregate sectional areas should ordinarily be greater after division than before. The total drop in voltage from power house or feeding point to a customer's lamp or motor is also usually less than the sum of the maximum drops in the parts of the circuit which are in series (such as house wiring, services, secondary mians, etc.) because these component drops do not have their maximum value simultaneously.

Stresses on Poles. — An overhead line is a framed structure. The poles are struts resisting the weight of wires, including sleet on the conductors, etc., insulators, cross arms and transformers and the downward pull of the guy wires. The horizontal pull of the line wires is balanced by the horizontal component of the pull of the guy wires, which transmit it to the ground. In addition to being struts the poles resist certain bending stresses, but these should be but a small part of the normal horizontal tension of the wires. The principal normal bending stresses are of two classes: (1) constant stresses, due to the unbalanced pull of service and other wires which do not exert sufficient force to require guys, and (2) variable stresses, due to the force of the wind at right angles to the line on both the poles and the wires. Poles also resist a twisting force where the tension on one side of an arm is greater than on the other, due to a difference in the number or weight of wires ending on the two sides. The poles, wires and guys should be so disposed that the bending and twisting forces on the poles are insignificant. The calculation of the strains produced in a pole is given in the article on Poles

Arrangement of Wires on Poles.— The arrangement of wires is governed by mechanical, electrical and practical considerations. For mechanical reasons it is desirable that:

1. The largest wires be on the lowest cross arm, in order to reduce the bending stress on the pole to a minimum.
2. The largest wires be on the pins nearest the pole, in order to reduce the bending stress on the cross arm to a minimum.
3. The wires be arranged symmetrically on the two sides of the pole, especially those which end at the pole, in order to reduce the twisting stress on the pole to a minimum

For electrical reasons (which, however, are of minor importance) it is desirable that:

4. The wires of any one circuit be as close together as practicable (on adjacent pins), in order to reduce the self-inductance of the circuit.
5. The wires of a three-phase circuit be arranged to form the edges of an equilateral prism and the wires of a two-phase circuit be arranged to form the edges of a square prism, in order to render the inductances and capacities of the wires respectively equal.
6. The wires of different circuits be placed as far apart as practicable, in order to reduce their mutual inductance.

For practical reasons it is desirable that:

7. The highest voltage wires be on the top cross arms and on the pins farthest from the pole, in order to reduce the danger of accident to linemen.
8. The mains, which have the greatest number of taps, be on the lowest cross arms, in order to avoid danger of accidental crossing (with contact) of the wires.
9. The arrangement be systematic throughout; this is absolutely essential for safe and economical operation.

As it is impossible to meet all of these conditions the actual arrangements used are compromises and are governed by the relative importance attached to the several desirable conditions. In some cases the electrical requirements (4) to (6) have been considered of most importance, resulting, for example, in an arrangement subordinated to the idea that the three wires of a three-phase circuit must be arranged exactly in an equilateral triangle. It appears, however, that these electrical requirements are really the least important of the considerations and that in most practical cases can be entirely neglected.

Transpositions. — Due to the effect of mutual electromagnetic induction (*see Inductance*) an alternating or varying current flowing in one circuit will induce a voltage, and therefore a current, in any parallel circuit; and due to the effect of mutual electrostatic induction (*see Capacity*) an alternating or varying voltage in one circuit will induce currents in a parallel circuit, even though there is no metallic connection between the two circuits. It is possible, however, by properly transposing equal alternate lengths of the wires forming the two sides of each of the parallel circuits, to neutralize these effects. Fig. 1 shows diagrammatically a scheme of transposition whereby a two-wire circuit can be protected from both electromagnetic and electrostatic induction from a parallel circuit and vice versa, provided neither circuit is grounded. The more frequent the transpositions the more thoroughly are the effects due to inequality in the spacing of wires and poles eliminated. Transpositions cannot be made effective in eliminating inductive effects when either circuit is grounded, otherwise than at the neutral point. See also *Transmission Lines*.

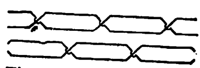

Fig. 1. Transposition of Two Two-wire Circuits

Methods of calculating the induced voltage and induced currents in one line due to currents and voltage in a neighboring line are indicated in the articles on *Inductance* and *Capacity*.

Disturbances in Telephone Circuits due to neighboring power circuits are the most common results of electromagnetic and electrostatic induction. When the power circuit is grounded and carries either (1) fluctuating direct currents (e.g., a d-c. railway) or (2) alternating currents it may produce a noise in the telephone receiver, even though both the power circuit and telephone line are transposed. See also *Telephone Lines*.

Trees. — Trees constitute the most serious obstacle to the proper planning, construction and operation of overhead lines. The principal methods of meeting this difficulty are (1) avoiding them, (2) going over them, (3) going under them, (4) going through them. In most cases a combination of these methods is used. Where trees are a serious factor it is necessary to examine the route of every line in detail and the size and location of the trees may become the determining feature of the whole design. In such cases nearly all rules of good construction and systematic arrangements are violated in the interests of expediency.

The methods by which trees may be avoided are: using alleys instead of streets, or vice versa, choosing streets without trees for important lines, taking side of street with fewest trees, and finally the very bad arrangement of crossing the street back and forth to avoid the trees either individually or in groups.

The plan of going over the trees is the proper one in the case of all small trees and is perfectly satisfactory until the trees grow up and touch the wires. It is therefore only a temporary method, especially where the trees are of tall, quick growing varieties. In going over small trees it is well to have poles tall enough to allow for wires clearing after several years growth. It is usually impracticable to go over large full-grown trees because of cost of poles, unsightliness of very tall poles, and the difficulty of properly guying them to resist wind and the unbalanced pull of wires, which is magnified by the great leverage. It is also difficult or impracticable to take off service wires over the tops of tall trees.

In the case of very large trees it is sometimes practicable to take the wires under the trees on short poles. Where the wires pass the trunks it may be necessary to spread them or necessary to pass between large branches, with insulators fastened to the trees to maintain clearance. While such a line may be kept fairly clear under normal conditions, there is apt to be trouble during storms from branches falling on the wires or from limbs bent by wind or snow touching them.

With trees of moderate size it is usually necessary to take the wires through the trees among the leaves and small branches. Such wires are a constant source of trouble and expense. The branches and leaves should be trimmed from around the wires as much as possible, including not only those in contact with the wires but such as will be brought into contact by wind or which will grow into contact during the season. In addition it is usual to protect the wires in the worse places by tree insulation consisting of split tubes of wood or bamboo.

Pole Transformers. — The primary (1100- or 2200-volt) mains are usually run to transformers mounted on poles and the voltage there stepped down to the lamp or motor voltage (110 or 220 volts), and secondary mains run from the transformer to the buildings in the immediate vicinity. These transformers usually range in size from ½ to 50 kw., but transformers of ¼ kw. were formerly common and transformers larger than 50 kw. are sometimes used in factory

together) does not have to be considered. Very small transformers are objectionable because of their poor regulation, lower reliability and the cost of frequently changing them as the load increases.

Use of Single and Polyphase Transformers. — Transformers are usually of the single-phase type, two being used for motors on two-phase circuits and two for small motors and three for large motors on three-phase circuits. Three-phase transformers are also used for motors on three-phase circuits, and have the advantage of reducing the amount of wiring on the poles. Single-phase transformers have the advantage of being interchangeable between the single-phase lighting and polyphase power circuits where the same voltage is used.

Voltage Ratios of Pole Transformers. — Lighting transformers were early standardized with voltage ratios based on multiples or submultiples of 10 : 1, that is, 1000 and 2000 volts primary to 50, 100 or 200 volts secondary, or 1040 and 2080 primary to 52, 104 and 208 volts secondary. It was found that on account of the voltage drop in the transformers and secondary mains, motors wound for this voltage did not operate well. Instead of remedying this difficulty by winding the motors for a lower voltage or by raising the voltage on the generators and lamps, power transformers were introduced with windings based on a ratio of 9 : 1 thus giving with 1040/2080 volts primary a secondary voltage of approximately 115/230. It was soon found that many complications followed from the use of transformers of the two ratios, so that companies dropped one or the other ratio and made their transformers interchangeable. Of the two ratios the 10 : 1 ratio is preferable, because it is the more extensively used, gives a higher voltage for primary distribution and agrees better with the general principles according to which voltages have been standardized.

Service Wires. — The service wires are those which connect the house wiring with the main on the street. Usually these wires extend in a single span from the nearest pole to the house. At the house they are fastened to insulators similar to those used on the line and mounted on brackets attached to the house. These brackets are often the ordinary wooden bracket used in line work, though the special iron brackets made for the purpose are neater and more secure. The bracket should take the strain off the service span, so that where the service passes through the wall it will not be under the strain of the span. The wires should pass through the wall in porcelain bushings and should have a drip loop between the bracket and bushing so that water will not follow the wire into the building. Where service wires do not conveniently reach the house at point of entrance, they are carried along the wall to such point, being supported at intervals by insulators on brackets. See also *Wiring of Buildings*.

At the pole the service wires are sometimes attached directly to the mains that supply them; while this is the easiest method it has the disadvantage that the strain in the service wire will come on the mains, which may also be injured by the attaching and detaching of numerous service wires. When the service wires do not slope upward or downward at a considerable angle they are liable to become crossed with the main of opposite polarity. Since the general direction of the service wire is at right angles to the main, the service wire should naturally originate on a cross arm at right angles to the arm carrying the mains. In good service work consequently a cross arm is attached to the pole below the main, and all the service wires to both sides of the street run from this. One tap to each of the wires constituting the main can then be used for a number of service wires.

Front and Rear Servicing. — When houses are serviced from a pole line on the street the service wires usually enter the front of the house while if serviced from alley they enter the rear. Service wires can be run around detached houses from front to rear on brackets on the wall, but this is unsightly, expensive and increases the service wire drop. Service entrances can be changed by changing the inside wiring, but the expense is usually heavy and the damage to decoration of rooms sometimes makes it prohibitive. In the wiring of a building the error is frequently made of bringing out services without regard to location of supply lines.

Attic and Basement Servicing. — The service-wire entrance and the center of distribution in the house is generally in the attic for houses serviced overhead and in basement for those serviced underground. Buildings arranged for underground service are sometimes supplied from overhead lines by taking service wires down poles and under sidewalks in iron pipes.

In changing an existing system from a street to an alley distribution, or from overhead to underground service, the center of distribution in the house must be correspondingly changed, or a connection run from the new service entrance to old center of distribution large enough to carry the current without unduly increasing the drop.

Sectionalizing of Distribution Circuits, Fuses and Cut-Outs. — An overhead alternating-current system supplied from a single bus is sectionalized: (1) at the switchboard in power station or substation into circuits having no external interconnection by knife switches or oil switches with fuses or automatic trip; (2) at the poles where long branches leave, by transformer cut-outs, either fused or solid, or by pole-type oil switches; (3) at transformer primaries by fused cut-outs. Switches and fuses are used but sparingly in the primary mains, and in a small compact circuit none are necessary. No switches or fuses are ordinarily used on the secondary side of transformers or on secondary mains. Occasionally transformers have been provided with switches in secondary side so that part of the transformers on a network could be cut out during times of light load to save core-loss. Such sectionalizing has been little used, as the small savings have not justified the complication, care and hazard to service due to mistakes.

When several transformers feed the same secondary main, the opening of a primary cut-out, either by blowing of fuse or by hand, does not make the transformer primary dead, as it is still alive from the secondary side. In case the fuse of one transformer on a secondary network blows the additional load thrown on an adjacent transformer may cause the fuse of that to blow, and all transformers to go out in succession. Under these conditions the fuses cannot be replaced in one transformer at a time. To avoid the interruption to service involved in leaving the fuses out until a time of day when one transformer can carry the whole load temporarily, or in having the whole primary circuit out while the fuses are replaced, it is sometimes possible to have all the transformers on a single secondary network on the same branch of the primary main, this branch being sectionalized from the rest of the primary circuit by a switch.

Lightning Protection. — (*See also article on Lightning Protectors.*) Practically all disturbances from lightning enter a system through the overhead distributing circuits. The most serious effects are not to the distributing circuit itself but to the switchboard and machinery in the station. The effects on the circuit consist of splitting of poles, puncturing of insulators, puncturing of transformers, blowing of transformer fuses. There may also be damage to meters or appliances on the premises of consumers. The protection principally used includes (1) lightning arresters and choke coils in the station (prin-

cipally to protect station apparatus), (2) lightning arresters at intervals on the lines, (3) ground wires over the lines, (4) lightning rods on poles and (5) grounding of the circuit.

Use of Lightning Arresters. — On alternating circuits lightning arresters are used at intervals on the primary but not on the secondary circuits. The amount of line which a lightning arrester will protect is less the more severe the lightning discharge. It is impracticable, and probably impossible, to space the arresters close enough together to absolutely protect a circuit. Theoretically the number of arresters used should be such that the sum of the loss due to the damage by lightning and the expense of providing and maintaining arresters to avoid damage is a minimum. The effects of lightning are too variable and the money loss due to interruption of service is too indeterminate to admit of correct distribution of arresters being determined by calculation. In practice it has been found that when no arresters are used many lightning discharges of considerable intensity do no great amount of damage, also that where the arresters are used much of the damage done is to the arresters themselves, and that their failure is a cause of a considerable number of interruptions to service. It is usually well to begin by using arresters sparingly on the lines and putting additional arresters on if found necessary. The maximum number of arresters would be reached when one was provided for each transformer bank.

The importance of lightning protection is greatest in a composite system, and in most cases underground or submarine cables should be protected by lightning arresters wherever they connect to exposed overhead circuits.

Ground wires are principally used over transmission lines but may be used to advantage over city distribution wires in exposed places. Where adjoining buildings and trees are higher than the pole line, these foreign objects answer the same purpose and little additional screening effect will be obtained from a special ground wire.

RECORDS OF CIRCUITS. — Overhead line construction is constantly changing due to erection, moving and removal of poles, extension of mains, connection and disconnection of service, erection and changing of location and size of transformers. The ease with which changes may be made in the lines necessitates a system of records in such form that any details can be changed at frequent intervals without making a completely new record. The great amount of complicated detail subject to frequent change makes it impracticable to record every feature. In compiling a system of records it is therefore important to determine: (1) what features should be recorded and what omitted, (2) a method of recording information which will be easily corrected. Written records and maps are both used, though for most purposes the latter gives a clearer, more comprehensive and useful record.

Maps of circuits have usually become useless, soon after they have been prepared either because obsolete from lack of correction or unintelligible because of successive erasures and interlineations. The following method of keeping map records has been found to give good results: (1) a map of the circuits is prepared on tracing cloth, giving the circuits on the date of preparation; (2) a blue print is taken from this tracing and all changes marked in pencil or crayon on this print, the print and not the tracing being used for correcting and reference; the tracing is not subject to wear or tear; (3) before the blue print becomes illegible from correction or wear the accumulated corrections are made on the tracing and a new up-to-date blue print substituted, and the process repeated. The corrections on the blue print can be made by line foremen or other unskillful persons, at the time that the line changes are made, while those on the tracing should be made by a draftsman who will make them neatly

and with minimum damage to the cloth. If no colored inks are used on parts subject to change, such a tracing will last a long time and will only have to be redrawn when changes have become so numerous or radical as to amount to a rebuilding of the circuits.

COST OF DISTRIBUTION CIRCUITS. — So many varying items enter into the cost of a complete distribution system that it is impossible to give comprehensive figures of general application. A cost of from $100 to $200 per kilowatt of maximum load at the distributing switchboard may be taken as an indication of the magnitude of the total cost of an overhead distribution system for both light and power, including all outside construction from the power station or the substation to the customer's service inlet, including meters.

DISTRIBUTION AND TRANSMISSION SYSTEMS. — (*See also Alternating Currents; Conduits and Conduit Lines; Distribution Lines; Electricity and Magnetism, Principles of; Ground Connections; Grounding of Electric Circuits; Insulators for Overhead Lines; Insulator Pins; Poles for Overhead Lines; Power Stations; Substations; Transmission Lines; Trolley Systems; Wiring of Buildings; Wires and Cables.*)

This article treats of the following subjects:

The design and construction of pole lines and underground circuits are treated in detail in the articles on *Distribution Lines, Conduits and Conduit Lines, Transmission Lines, and Wiring of Buildings.* Requirements regarding the grounding of circuits and methods of making ground connections are treated in the articles on *Grounding of Electric Circuits* and *Ground Connections.*

Circuits designed for transmitting relatively large amounts of power from one fixed point to another are called transmission lines, while those for delivering small amounts at numerous points are called distribution circuits. Transmission lines usually have no or few branches, while it is characteristic of distribution circuits to have many branches. The various systems of transmitting and distributing electric energy for light and power may be classified under two general heads, viz., constant current or series and constant potential or multiple systems, and each of these may be subdivided into direct-current systems and alternating-current systems.

CONSTANT CURRENT OR SERIES SYSTEM. — The lamps or other devices are connected in series and the current through them is kept constant, the voltages varying automatically to increase or decrease the energy delivered. It is the principal system used in the United States for street lighting, but is now little used for any other purpose. At one time such circuits were extensively used for commercial arc lighting in stores, but the series arc became obsolete for commercial use when the arc lamp was perfected for use in multiple circuits. The value of the current used for street lighting ranges from 1.75 to 9.6 amp., depending upon the type of lamp used.

Source of Current. — Direct current for series circuits is usually obtained from d-c. series generators (*see Generators, Direct-Current*) or from an a-c. circuit by rectifying the alternating current from a constant-current transformer (*see Rectifiers*); adjustable resistance in series in a constant potential d-c. circuit is sometimes used. Alternating current is usually obtained from a constant-current transformer on a constant potential a-c. circuit; other methods sometimes used are an adjustable resistance or reactance in series on constant potential a-c. circuits and by automatic regulating reactance coil on a constant potential a-c. circuit.

Cut-Outs, By-Passes and Transformers. — Switching out of lamps on series circuits is accomplished by short-circuiting them; this leaves the lamps charged to the potential of that point in the circuit. To make them safe to handle "absolute cut-outs" are used which also disconnect both conductors to the lamp, leaving the circuit closed.

To avoid the excessively high voltage which would occur when the circuit opened, due to series incandescent lamps burning out, an automatic by-pass is provided in multiple with the lamps, sometimes consisting of a piece of paper which punctures on a moderate rise of voltage, or of a choke coil which takes but little current at normal lamp voltage. Sockets for series incandescent lamps are arranged to automatically close the circuit when the lamp is withdrawn.

Transformers, one at each lamp, are sometimes used to insulate the secondary circuit containing the lamp from the primary or for reducing the current for low-current lamps used in series with lamps taking higher current.

Advantages and Disadvantages of Series Lighting. — Constant current or series systems have the advantage that low-voltage lamps may be used on high-voltage circuits without the expense, losses or complication of transformation. They have the disadvantage that the lamps are dangerous to handle, the efficiency is low at light loads and it is impracticable to distribute any large amount of power on a single circuit. In the series system the current and consequently the loss in the conductor is the same irrespective of the load, while in the multiple system, the current is proportional to the load, and the watts lost in the line therefore vary as the square of the load and the per cent loss directly as the load. For this reason the series system is not an economical one where the load varies and averages much below full load, which is the case with most commercial loads. For street lighting where all the lamps are turned on and off at once the efficiency at partial loads is of no importance. In constant-current systems the resistance of the circuit does not affect the uniformity of the voltage on the lamps at different parts of the circuit, while with constant-potential systems it does. For a scattering load of lamps, such as street lamps, a uniform light can therefore be obtained from the several lamps, with a much smaller weight of copper and fewer wires by using the series than by using the multiple system.

Thury System. — In Europe the constant-current or series system, with direct current of extra high voltage, has been used for long-distance power transmission under the name "Thury System." The current is obtained by connecting several generators in series, and is utilized by a number of motors also in series. The advantages are simple switchboards, no transformers and minimum strain on line insulators, the latter due first to the fact that in direct current the effective voltage is as high as the maximum voltage, and second, that in a constant-current system the working voltage only remains at its maximum value during the short period when the load is also a maximum. Among the disadvantages are the necessity for insulating frames of generators and motors, need of speed governors on motors, necessity of converting the current by moving machinery in every case where it is used for lighting and in most cases for power. The Thury System is not used in the United States.

CONSTANT-POTENTIAL OR MULTIPLE SYSTEM. — In this system, which is the one principally used for electrical distribution, the voltage between conductors is kept as constant as practicable and the current varies as the load changes. The degree to which the voltage approximates constancy throughout the system is called the "regulation" of the system.

Use of Direct or Alternating Current. — Either direct or alternating current can be used equally well for certain purposes, principally those for which the

heating effect of the current is used, including the lighting of carbon and tungsten incandescent lamps, cooking and heating. For certain purposes, where the current effects chemical or physical changes, such as charging storage batteries and electroplating, direct current is essential; for other purposes, such as operating arc lamps and tantalum incandescent lamps, it is better; whereas for other purposes, such as for Nernst lamps, the alternating current is better. For motive power, the direct current is most favorable where acceleration, variable speed and adjustable speed are desirable, whereas alternating current gives best results where uniform unvarying speed is desired. While the fields of the two kinds overlap to such a large extent that either kind can be used for general distribution, it is found that it is often more advantageous to use both. For low-voltage, underground distribution, direct current is advantageous because the heavy currents can best be carried on single conductor cables; no subway transformers and no small, high tension fuses are required.

Alternating current may be supplied either directly from the generators in the power station or from the secondaries of transformers in substations. Direct current may be supplied either directly from direct-current generators or from converter substations (*see Substations, Railway*) supplied with high-voltage alternating current.

Light and Power Circuits. — For a load consisting of both electric lamps and electric motors the same circuit may be used throughout for both classes of service or entirely or partially independent circuits may be employed. The use of the same circuit throughout for light and power service has the advantages of reduced number of wires, transformers and meters, reduced weight of wire, and reduced capacity of transformers and meters, whereas the use of separate circuits for light and power has the advantage of requiring less capacity of feeder regulators and, sometimes, of less weight of wire for the same perfection of regulation on the lighting circuits and also simplifies the problem of balancing the phases in polyphase distribution (*see below*). In the business districts of many cities the Edison three-wire direct-current system is used, in which case light and power are usually supplied from the same circuit, the motors as a rule being connected to the outside wires. In business districts where the lighting is done by alternating current the lighting is frequently on single-phase circuits and the power on separate polyphase circuits or on 500-volt direct-current circuits. In residential districts, where the lighting is done by single-phase alternating current, small motors are usually put on same services as the lights; whereas larger motors (from 1 to 5 and in some instances as large as 15 horse-power) are put on separate meters, services and transformers, but the same primaries are used for both services. In factory districts when the power is the predominating load and is supplied by polyphase circuits the incidental lighting is sometimes taken off the same services, but usually there are separate meters and transformers. There are a large number of cases where the same polyphase primaries are used for power and light with separate transformers and secondaries; in these cases the lighting transformers are usually distributed as equally as convenient between the several phases, in order to balance the load, though occasionally they are all connected to a single phase. In a few cases the same secondaries have been used for power and light usually on the four-wire three-phase plan.

Circuits with Branches. — There are two methods of providing proper distribution circuits for an extensive area, known respectively as the "tree system" and the feeder and main system. The former is the most extensively used but is not susceptible of providing as good voltage regulation as the latter.

Tree System; Interconnected Networks.— The simplest method of constant-potential distribution is to run one set of wires through the middle of

the district to be served, running branch wires from them wherever convenient for reaching loads at the sides. At the beginning, the single set of wires is large enough to carry the whole current, but the size is diminished as the current branches off. In this system adjacent branches will often have widely different voltages, due to unequal drop because of varying loads. If wires are run connecting the out-lying ends, currents will flow and partially equalize the differences in voltage. This plan, if carried out systematically, develops into a network, usually composed of two sets of parallel mains crossing at right angles and connected at each point of crossing.

Feeder and Main System. — It is practicable to keep the voltage on the customers' electric lamps within 2 to 5 per cent of being constant, even when it is necessary to raise the voltage of the generators from 10 to 20 per cent, from no load to full load, by arranging the distribution circuits on the feeder and main plan. The area to be served is first divided into compact sections; each small enough to be fed from a central point with a voltage drop within the desired percentage. A system of wires called "mains" are run from this central point, called the "feeding point," or "distribution center," to the customers. The mains form a little circuit originating at the feeding point instead of at the power house; they may be arranged on either the tree or interconnected network plan. A set of wires called "feeders" is run from the power house to the feeding point. As no current is taken off at intermediate points, these wires are not tapered and any desired drop of voltage may occur in the feeders without affecting the lamps, provided the power-house voltage is raised proportionally.

Two-wire System. — The simplest multiple system is the two-wire system, where all devices are connected directly in multiple. This system is used very extensively for direct-current light and power, from isolated plants, for power circuits (usually 500 volts) and railway circuits from central stations. It is also used for single-phase alternating-current distribution for both primary and secondary circuits.

Edison Three-wire System. — The three-wire system, Fig. 1, is obtained by replacing the out-going wire of one two-wire system and the return wire of a second two-wire system by a single wire, called the "neutral." The voltage between the outside wires is then double the voltage between the neutral and either outside wire. For example, 110-volt lamps may be connected between the neutral and either outside wire, and 220-volt motors may be connected between the two outside wires, and both the lamps and motors be supplied with their rated voltage. The neutral wire carries a current which depends only upon the *difference* in the loads on the two sides of the system and their distribution. As a rule the neutral of a three-wire main is made equal in cross-section to each outside wire. With perfectly balanced load the three-wire system with all three wires of the same size results in a saving in copper of 62.5 per cent as compared with a two-wire system supplying the same load at the same regulation.

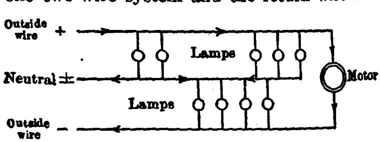

Fig. 1. Three-wire System

The three-wire system is used very extensively for direct-current light and power distribution from central stations, also for large isolated plants and for alternating current for lighting on the secondary circuit. Three-wire systems are usually 110 volts on each side of neutral, or 220 volts between outsides,

though there are several systems using 220 volts on each side and 440 volts between outsides.

The Edison three-wire distribution system, as used in the business sections of large cities, consists of a set of interconnected three-wire mains supplied by two-wire or three-wire feeders from one or more power houses or substations. The different feeders feed into the same set of mains at different points. At the power house or substation end the feeders are often all supplied from a common bus, though where there is a great difference in the length of the feeders there are sometimes two busses which are run in multiple when the load is light but separated when it is heavy, the short feeders on one called the "low bus," and the long feeders on the other called the "high bus," because of the relative voltages. As the feeders from the several substations connect to interconnected mains, the bus voltage in each is raised or lowered in accordance with the drop in its own feeders. All mains which connect feeding points supplied from a given bus are made large enough to allow large equalizing currents to flow through them, without requiring any great drop in the mains, in order to equalize the voltages at these points.

ALTERNATING-CURRENT SYSTEMS. — The simplest form of alternating-current system is the single-phase system, for which the connections are exactly the same as for the direct-current systems. Both two-wire and three-wire circuits are used, the former for primary circuits and small secondary circuits and branches, and the latter for large secondary circuits. The principal use of single-phase circuits is for electric lighting and auxiliary uses, such as heating or cooking, and fan motors. For delivering large amounts of power a two-phase or three-phase system is generally used.

Two-phase Systems. — In this system there are two single-phase currents having a difference in phase of 90°, or a quarter of a cycle. These currents may be distributed on the three-wire, four-wire or five-wire system; see also under *Transformer Connections* in the article on *Transformers*.

Three-wire Two-phase Systems. — Each single-phase current has a separate outgoing wire but unites in a common return wire. Each two-phase motor has two circuits, each connected between an outside wire and the return wire. The voltage between the two outside wires is 41 per cent greater than between outside wire and return wire and the current in the return wire is 41 per cent greater than in each outside wire. This is an unsymmetrical system and has the disadvantage that even a balanced load will cause a distortion and unbalancing of the delivered voltage of the two phases because of the unsymmetrical drop in the common return wire.

Four-wire Two-phase System. — Each of the two single-phase circuits has a complete, independent two-wire circuit. There are two variations, first where the circuits are insulated from each other, in which case a cross between either wire of one circuit with either wire of the other will change the voltage stress to ground, but will not affect the delivered voltage or cause a short circuit; second, when the neutrals of the two circuits are connected. In the latter case, from each wire of one circuit to either wire of the other circuit, the voltage is 71 per cent of the voltage between wires of the same phase. The four-wire system with insulated phases is probably the most extensively used of the two-phase systems.

Five-wire Two-phase System. — This is a modification of the four-wire system, with interconnected neutral in which the common neutral is extended as a fifth wire. Lamps may be connected from each of the four wires to the neutral. The five-wire system may be considered as two three-wire single-phase systems, one for each phase, with a common neutral wire.

Three-phase Systems. — In this system there are three single-phase alternating currents with a phase difference of 120°, or of one-third of a cycle. These currents may be distributed on the three-, four- or six-wire systems.

Three-wire Three-phase System. — Each single-phase current has a separate outgoing wire; the three return currents neutralize so that no return wire is required. The three wires are necessarily interconnected, the voltages are usually the same between any two and the currents equal in each of the three conductors, provided the loads on the three phases are equal, i.e., provided the load is balanced. When equally loaded the voltage drops in the three conductors are equal and symmetrical. This is the most extensively used of the three-phase systems.

Four-wire Three-phase System. — This is a modification of the three-wire system in which a neutral wire is extended as a fourth wire. Lamps or transformers may be connected from each of the three wires to the neutral, which carries only the unbalanced current, due to the differences in loading of the three phases. The voltage between the three outside wires is 73 per cent greater than from each outside wire to neutral.

Six-wire Three-phase System. — If to a three-wire, three-phase system, three wires are added, one with voltage midway between that of each pair of outside wires, lamps may be divided into six groups, between the three outside wires and the three adjacent middle wires. The result is the same as though there were three single-phase three-wire circuits, one for each phase, with the six outside wires combined in pairs giving three common outside wires in place of the three pairs. When connected in this way, the three middle wires cease to be neutrals, as between the three there is a three-phase voltage equal to one-half of that between the three outside wires.

Six-phase System. — This is used for circuits in the interior of substations (q.v.), such as from transformers to rotary converters, but is not used for distribution.

Monocyclic System. — This is a variety of unsymmetrical polyphase system now obsolete. It may be regarded as a species of two-phase system with voltage on one phase one-fourth of that on the other and with the two wires of the larger phase acting as a common return for the small phase.

Star or Y, and Mesh or Δ Connections. — See article on *Alternating Currents*.

Transformer Connections and Phase Transformations. — See article on *Transformers*.

Transformations of Systems. — Any electric system can be transformed to any other electric system by the use of rotating machinery; see *Motor-Generators* and *Converters, Synchronous*. This method is used chiefly for changing from alternating to direct current and for changing the frequency of alternating current. Conversion from alternating to direct current is also accomplished by means of mercury arc rectifiers, particularly for series d-c. arc lighting and for charging storage batteries; see *Rectifiers*. Conversion from any alternating voltage to any other alternating voltage at the same frequency is accomplished by means of transformers (q.v.).

Frequencies in Use in the United States. — At present the two frequencies in most general use and adopted as standards in most new work are:

60 cycles per second or 7200 alternations per minute, used by the majority of companies operating alternating-current lighting systems.

25 cycles per second or 3000 alternations, generally used for alternating-current railway or power work or where the alternating current is to be converted into direct current before final use.

In addition to the above other frequencies ranging from 140 to 25 cycles per second are in use as follows:

140 cycles or 16,800 alternations. Formerly standard frequency of Ft. Wayne electrical works, now obsolete for new apparatus but still used in many small towns.

133⅓ cycles or 16,000 alternations. Formerly a standard frequency of Westinghouse E. & M. Co., and Stanley Co., now obsolete for new apparatus but still used in many small towns.

125 cycles or 15,000 alternations. Formerly a standard frequency of General Electric Co., now obsolete for new apparatus but still used in many small towns.

50 cycles or 6000 alternations. Used extensively in several large systems in Southern California.

40 cycles or 4800 alternations. A compromise frequency at one time standard with the General Electric Co. used on several large systems in that part of New York state around Albany and including the General Electric Co.'s system at Schenectady. Also used by certain mills in New England and elsewhere.

35 cycles or 4200 alternations. Used on the large system of the T.C.R.T. Co., in Minneapolis and St. Paul.

33⅓ cycles or 4000 alternations. Used by the P.G.E. Co., in Portland, Oregon.

16⅔ cycles or 2000 alternations and 15 cycles or 1800 alternations have been proposed for use on single-phase electric railway work and it has even been suggested that they be standardized for that purpose but at the present time practically no progress has been made toward their introduction.

Choice of Frequency. — For new light and power systems, the choice of frequency depends on (1) the frequency of existing systems in same or adjoining territory, and (2) the proportion of load which will be direct current. It is generally advantageous to have a new system of the same frequency as that of existing systems in the same or adjoining territory, so that a physical connection can be made between them or load transferred from one to the other without the use of frequency changers. The choice of frequency now (1914) is in most cases confined to the two standard frequencies, 60 and 25 cycles. Aside from the question of matching adjacent systems, the choice depends principally on the proportion of current to be converted into direct current. Where all load is direct current, 25 cycles has the advantage; where all load is alternating-current lighting, 60 cycles is best.

Use of Two Frequencies. — When the bulk of the load is direct current, but a small though important part is alternating-current lighting, two frequencies, 25 and 60 cycles, are sometimes used. Sometimes the two frequencies are generated by separate prime movers, though sometimes all current is generated at 25 cycles and the 60-cycle current obtained from frequency changers (*see Motor Generators*).

RELATIVE VOLTAGES AND WEIGHTS OF COPPER REQUIRED FOR VARIOUS SYSTEMS. — The comparison of the various systems with respect to the weight of copper required, as tabulated below, is based upon the assumptions (1) that the energy delivered, (2) that the energy loss and (3) that the maximum voltage strain on insulation between any wire and ground are respectively *the same* for all systems.

When the neutral or middle point of the system is grounded, then the maximum voltage strain on the insulation to ground is the maximum instantaneous value of the voltage between any outside wire and neutral. In the case of an alternating sine wave of voltage the maximum instantaneous value is equal to $\sqrt{2}$ times the effective value determined by a voltmeter. When the neutral is not grounded then an accidental ground on any leg will throw full line voltage across the insulation between any other leg and ground.

On this basis of comparison, assuming a sine wave of voltage and 100 per cent power factor for the alternating-current systems, the relative voltages between outside wires and the relative weights of copper are as follows:

RELATIVE VOLTAGES AND RELATIVE WEIGHTS OF COPPER

System*	Relative voltages between outers		Relative weights of copper*	
	Grounded neutral	Insulated neutral	Grounded neutral	Insulated neutral
	Per cent	Per cent	Per cent	Per cent
Direct-current (2-wire)	100	50	100	400
Single-phase (2-wire)	71	35.5	200	800
Two-phase (4-wire)............	71	35.5	200	800
Three-phase (3-wire)	61	35.5	200	600

* Neutral wire not included; when neutral is added increase the figures given in the ratio of weight of neutral to combined weight of the outside wires for the system in question. For example, the addition of a neutral wire equal in size to either outside wire to a d-c. 2-wire system with grounded neutral gives a relative weight of copper of $100 \times 1.5 = 150$ per cent.

Effect of Power Factor. — To correct the above tabulation for alternating-current systems in cases where the power factor is less than unity divide the relative weight of copper given by the square of the power factor (i.e., for a single-phase two-wire system with insulated neutral and 70 per cent power factor the weight of copper will be $800/0.70^2 = 1630$).

VOLTAGES FOR D-C. AND A-C. SYSTEMS. — Unless otherwise specified the "voltage" of a polyphase system refers to the potential difference between adjacent outside wires; see *Alternating Currents* for the relations between the various voltages.

A considerable number of voltages are standard or semi-standard. In general they may be considered as derived from a lamp voltage of 50 or 100 multiplied by the factors 2, 3, 5 and 10, and increased by 4, 5, 10, 15 and 20 per cent for various reasons, principally to allow for line loss. In addition to this system of voltages there is another system which arises from the use of Y and Δ connections on the three-phase system; these voltages are related to the above by the factor $\sqrt{3} = 1.73$, either as a multiplier or a divisor. For example, the voltage between the outside wires of a four-wire three-phase system supplying 115-volt lamps connected between each outside wire and neutral is $\sqrt{3} \times 115 = 198$ volts.

Voltages Commonly Used. — The voltages most used are:

Direct current:

100 to 120 volts	Lighting, small power and field excitation.
200 to 240 volts	Power, lighting and field excitation.
500 to 600 volts	Power, electric railways.

Alternating current, secondary distribution:

100 to 120 volts	Lighting, small power.
200 to 240 volts	Power.
400 to 480 volts	Power.

Alternating current, primary distribution:

1000 to 1200 volts	Lighting (obsolete).
2000 to 2400 volts	Lighting and power.

Alternating current, intermediate distribution:

5000 to 6000 volts	Generating station to substation.
6000 to 7200 volts	Generating station to substation.
10000 to 12000 volts	Generating station to substation.
12000 to 13200 volts	Generating station to substation.

Alternating current, high tension transmission:

20000 to 24000 volts	Generating station to substation.
30000 to 36000 volts	Generating station to substation.
40000 to 48000 volts	Generating station to substation.
50000 to 60000 volts	Generating station to substation.
60000 to 72000 volts	Generating station to substation.
100000 to 110000 volts	Generating station to substation.

CIRCUITS FOR TYPICAL CITY DISTRIBUTION SYSTEM. — For a city covering a space ten miles square, with current generated at one point, a typical distribution would consist of the following lines: —

(1) From generating station to substations; alternating current, 60 cycles, three-phase, 11,000 volts.
(2) From lighting substations in business center; direct current, 110–220 volts, three-wire.
(3) From lighting substations in residence district; alternating current, 60 cycles, one-phase, 2200 volts for house lighting, and alternating current, 60 cycles, one-phase, 6.6 amperes series circuits for street lighting.
(4) From power substation in factory district; alternating current, 60 cycles, three-phase, 2200 volts.
(5) From railway substation; direct current, 550 volts.
(6) From secondaries of lighting transformers; alternating current, 110–220 volts, three-wire for large transformers and alternating current, 110 volts, two-wire for small transformers.
(7) From secondaries of power transformer; alternating current, 220 volts, three-phase.

EFFICIENCY OF DISTRIBUTION. — The ratio of the energy registered by the customers' meters, or which would be so registered if all customers had meters, to the energy supplied by the generator to the bus-bar in the generating station, may be called the over-all efficiency of distribution. The losses may be divided into several kinds: line loss, transformer loss, converter loss, meter loss and error, leakage and unaccounted for. For some purposes it is useful to consider each loss from two points of view: (1) as a loss of energy, and (2) as a loss of power at full load; the first may be called the energy loss and the second the capacity loss. The corresponding efficiencies are usually designated as all-day or energy efficiency and the full-load or capacity efficiency respectively.

Fixed and Variable Losses. — The total energy loss consists of two components, (1) a fixed loss independent of load, including the core-loss of transformers, the core-loss, excitation, friction and windage of rotating converting apparatus, the loss in the shunt coils of meters, the copper loss in constant current circuits, and the loss in the arc of mercury arc rectifiers for constant current circuits; (2) a variable loss proportional to the square of the current, including the copper loss of constant potential circuits and of transformers, and the armature copper loss of rotating converting apparatus. The effect of the fixed loss on the per cent efficiency depends on the load factor of the load, while

that of the variable loss depends both on the load factor and the shape of the load curve.

Representative Losses. — For a lighting system, the full-load losses in primary feeders, primary mains, transformers, secondary mains, services and meters may be expected to be as much as 17.5 per cent of the power generated and the daily energy loss 33.3 per cent of the energy generated, giving 82.5 per cent capacity efficiency and 66.7 per cent energy efficiency respectively.

Effect of Nature of Load. — In making estimates of the efficiencies of particular systems, the effect of the following items should be considered: (1) relation of transformer capacity to maximum loads, (2) load factor, (3) shape of load curve, (4) power factor, (5) diversity factor.

REGULATION. — An ideal constant potential distribution would have one uniform, unvarying voltage, and would be said to have perfect regulation. The greater the variation from such constancy the poorer the regulation. The regulation is usually specified in per cent variation, either "above or below" a standard mentioned. The standard is usually either the nominal voltage desired or the actual average voltage obtained.

Evil Effects of Poor Regulation. — The evil effects of high voltage are short life of electric lamps, excessive speed of direct-current motors, excessive exciting current of induction motors and burning out of motors and other devices; on the other hand, low voltage greatly diminishes both the candle-power and efficiency of electric lamps, decreases the maximum power of motors and increases the current which a motor will take for a fixed horse-power output. As electric lamps are much more sensitive to change of voltage than motors, separate circuits are often used for lighting and power, the former having devices for regulation which are omitted from the latter.

The following figures give roughly the quantitative effect of voltage variation between 5 per cent below and 5 per cent above normal:

Each per cent decrease in voltage decreases candle-power of carbon incandescent lamps	5 Per Cent
decreases torque of induction motor	2 Per Cent
Each per cent increase in voltage decreases the life of carbon incandescent lamps*	13 Per Cent
increases the magnetizing current of induction motors	2 Per Cent

Ordinary Limits of Regulation. — Roughly, the maximum voltage variation at the lamps on a lighting system should never exceed 5 per cent, i.e., the regulation above or below normal should never be greater than 2.5 per cent, and should be as much less as is economically feasible; the voltage variation on power systems is usually 10 per cent (5 per cent above or below normal) and is sometimes considerably more.

Calculation of Regulation. — In order to calculate the variation in voltage at any receiving device or group of such devices from no load to full load, the voltage at the generating or substation or feeding point being assumed constant, the impedance drops in all parts of the distribution system must be calculated and properly combined. The various parts of the system to be considered are the house wiring, service wires (or leads from street mains to the house), secondary mains, transformers, primary mains, primary feeders. See *Distribution Lines; Transmission Lines; Wiring of Buildings.*

In making such calculations account should be taken of the fact that the loads or currents in the several parts of the system seldom have their maximum

* Average for 5 per cent increase in voltage; the first per cent increase in voltage decreases the life 18 per cent, the fifth per cent 8 per cent.

values at the same time. The maximum drop in house wiring will not occur simultaneously in all houses nor will the maximum service drop occur together on all services, etc. Furthermore, the maximum house wiring drop for a given house may not occur at the same time as the maximum drop on the secondary mains, transformer or primary mains to which it is connected.

Effect of Line Reactance. — The regulation of an alternating-current system of unity power factor will be poorer than that of a direct-current system of the same copper efficiency (see tabulation above) because of additional drop due to line reactance.

Effect of Lagging Power Factor. — A lagging power factor usually makes the regulation of an alternating-current system worse than it would be for unity power factor and therefore much worse than for a direct-current system of the same copper efficiency.

Effect of Leading Power Factor. — A leading power factor usually makes the regulation better than it would be for unity power factor and may give even better regulation than can be obtained from a direct-current system of the same copper efficiency.

Effect of Currents in Neutral. — Any current in the neutral wire of a balanced system produces a drop which tends to unbalance the voltage of the two sides. In the case of a three-wire direct-current or single-phase system *one per cent drop in neutral produces two per cent difference in the voltages on the two sides.* Voltage drop in the neutral therefore affects more seriously the regulation than an equal amount in the outside wires. If the currents in the neutral all have the same direction, say toward the station, the voltage drops in the various parts of it will be cumulative, and though the drop in each section may be small and no current may actually reach the station, the aggregate effect may be serious. The individual loads on the two sides of the neutral should be connected so that the unavoidable neutral currents flow alternately in each direction, thus causing drops in alternate directions thereby neutralizing each other over the total length of the circuit.

Feeder Neutral in Three-wire Systems. — When the "feeder and main" system is used with a three-wire system, two-wire feeders should be used only on the outside wires, and only a single "feeder" neutral be used. That is, with respect to the neutral, the "tree" system gives better regulation for the same weight of copper than the "feeder and main" system, but with respect to the outside wires the latter system gives the better results. This is a point which has not always been recognized in laying out three-wire systems.

VOLTAGE CONTROL. — (*See also Controllers.*) The more common methods of controlling the voltage at feeding points when the feeder and main system of distribution is used (*see above*) are the single bus system, the high and low bus system, and feeder regulators.

Single Bus System. — (*See also article on Bus-Bars.*) All the feeders may be connected to a single bus and the bus voltage be raised as load increases so as to compensate for average drop of all the feeders on it. This method gives excessive voltage on such feeders as are comparatively short and low voltage on those that are long. Usually maximum voltage is carried in the evening during the lighting peak and lower voltage during day giving very poor regulation on power circuits having maximum load during the day and low load at night. This method is used on most small direct- and alternating-current distribution systems.

High and Low Bus System. — The bus may consist of two parts which may be separated, and operated at different voltages, feeders of greater average

drop connected to the "high" (voltage) bus and the others to the "low" (voltage) bus. The voltage of each bus is raised or lowered in accordance with average drop of feeders on it as in the single bus system. This method is used extensively on the Edison three-wire direct-current systems, as noted above. The unequal drop of the several feeders on same bus are equalized by heavy interconnection through mains.

Feeder Regulators. — A feeder may have a separate regulator adjustable to compensate for its own drop. This method is sometimes used on direct-current railway feeders and very extensively on alternating-current lighting feeders. See article on *Regulators*. A feeder or other distribution circuit which contains a voltage regulator is frequently referred to as a "boosted circuit." Boosted circuits are not usually interconnected but may be if the boosting is of the same nature in each.

Control of Polyphase Systems. — In a polyphase system the load may be as equally divided among the phases as possible and the voltage regulated with respect to any one phase taken as representing the average of all; or the lighting load may be connected on a single phase and the voltage regulated for this phase alone. The former method is more common, as it permits of full output of all the phases of the generator being used and gives a more equal voltage on the several phases of polyphase motors.

Transformers as Outside Boosters. — An auto-transformer or an ordinary transformer may be connected to a feeder at any point and used as a "booster" to raise or lower the voltage. In the case of an ordinary transformer the primary and secondary are connected in series thus converting the transformer into an auto-transformer; see article on *Auto-Transformers*. Such boosters are not adjustable and have a bad effect on the regulation as they give excessive voltage on the boosted part of line at light load.

To cut such a booster out of service without taking it off the circuit the primary coil must be open circuited and the secondary short circuited. *Caution:* the main circuit must be opened before cutting out booster, because if the primary is opened while current is flowing in the secondary the booster becomes a step-up transformer and may give a dangerously high voltage on the primary. If on the other hand the secondary is short circuited first, a destructive short-circuit current may flow through it and the primary, and when the primary is opened a dangerous arc will form.

Use of Lamps of Different Voltage. — Attempts have been made to compensate for the difference in voltage at the various points of a network by using lamps of different rated voltage, high-voltage lamps being used near the point of supply and low-voltage lamps at the ends of line. This plan has not been successful because the difference in voltage between any two points is not constant. Frequently some of the high-voltage lamps are used by mistake where low-voltage lamps are intended; the results are then poorer than when no difference is made in lamp voltage. While lamps of two or more voltages may be used temporarily as an expedient when regulation is very bad, it is better practice to have all lamps on a system of a single uniform voltage.

Use of Transformers of Different Ratio. — Transformers are also made with taps so that a uniform secondary voltage can be obtained with a varying primary voltage. The plan is not a good one, because if the difference in ratio is correct for uniform voltage at full load it gives unequal voltages at light load. It also has the very serious disadvantage that the haphazard changing of transformer ratios by ignorant linemen to compensate for dim light, due perhaps to lamps already blackened by excessive voltage, makes it impossible to carry out any systematic plan for securing the best average regulation for the system as a whole.

BALANCING OF LOAD. — In three-wire direct-current or single-phase systems and in all polyphase systems supplying single-phase load it is necessary to approximately balance the load between the two sides or the several phases as the case may be. Unbalanced load has two bad effects: (1) it loads the two sides or phases of the system unequally, making it impossible to get full output out of the lightly loaded side or phase without overloading the other; (2) it makes the regulation of the system worse by causing high voltage on the lightly loaded side or phase and low voltage on the other.

The first difficulty is not serious, because through the conduction of heat from the loaded to the unloaded coils of transformers and generators the machine capacity is not reduced in proportion to the unbalance; for moderate unbalancing, say up to 10 per cent greater load on one side or phase than on the other, it is doubtful if any appreciable effect could be discovered. As the total load usually consists of a great number of small parts, a very little foresight in dividing the load in the first place between the sides or phases, and in suitably distributing subsequently connected load, will give a balance good enough for all practical purposes. When polyphase alternators were first installed for supplying existing single-phase lighting circuits, it was supposed to be important to have a close balance of load between the phases, and early switchboards were therefore provided with transfer switches for throwing single-phase feeders from phase to phase. It was later found that instead of being necessary to transfer the load from phase to phase, following the diurnal or annual variations of load, that the circuits could stay on the same phase indefinitely and that transfer switches were unnecessary and undesirable. The time when rebalancing of this kind is necessary is usually when new circuits are established, at which time the changes of connections are best made by changing the taps to the bus-bars.

Motor-generator Balancer. — On direct-current three-wire systems the difference in current on the two sides may be balanced without taking the neutral current to the generator by a balancer consisting of two similar machines mechanically coupled and electrically connected in series. Each machine is wound for the voltage of one side of the system (110 volts for a 110/220-volt system); the common connection between the machines is connected to the neutral and the other two terminals to the two outsides, see Fig. 2 (the field windings are omitted for clearness). The unit acts as a motor generator (q.v.), whichever machine happens to be on the light side being the motor for the time being and the other the generator. By strengthening the field of the one on the side where the voltage is low and weakening that of the other, so as to keep the same total voltage, the voltages on the two sides as well as the currents may be balanced if necessary.

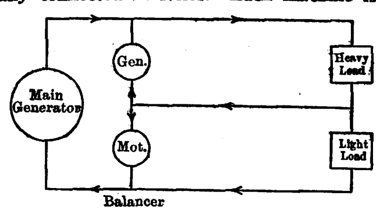

Fig. 2. Motor-generator Balancer

The output of the balancer generator and the input of the balancer motor are practically equal to each other, neglecting the losses in the machines, and each is equal to

$$\frac{P_1 - P_2}{2},$$

where P_1 is the load on the heavily loaded side of the system and P_2 the load on the lightly loaded side. For example, if the load on one side is 110 kw. and on the other side 90 kw., the load on each unit of the balancer is 10 kw.

It would, however, be unsafe to use a balancer as small as such calculations for the normal unbalancing would indicate as correct, because in case of a short-circuit on one side of the system, or of loss of a large amount of load on one side, due say to the blowing of fuses, the balancer would be dangerously overloaded. This may not only destroy the balancer, but may burn out many lamps and motors on one side due to excessive voltage. In small systems, say up to 100-kw. total capacity, the balancer should be able to operate momentarily with any loading up to the capacity of the main generator, and in large systems should have capacity sufficient to burn off a short-circuit on one side of the system without creating an unduly high voltage on the lightly loaded side.

Dynamotor as a Balancer. — A smaller and cheaper balancer is obtained by using a dynamotor (q.v.), which is a single machine with two windings on one armature and two commutators. The armatures are connected in series and balance the currents, but as there is only one field the voltages cannot be balanced.

Alternating-current Balancing Coil. — On alternating-current single-phase three-wire systems it is usual to obtain the neutral from the middle point of the coil of the transformer supplying the current. It can, however, be obtained at any point of the two-wire circuit without going back to the transformer by using a balance coil. A balance coil is a transformer with two similar windings connected in series across the circuit and with the neutral wire connected to the common point between the windings. Whichever coil is on the lightly loaded side acts as the primary and the other as the secondary, thereby balancing the circuit by transferring one-half of the difference in load from the heavily loaded side to the lightly loaded side. Such coils, which are essentially auto-transformers with a 2:1 ratio, may be used in various ways: to obtain the neutral for an unbalanced three-wire circuit from a two-wire circuit; to supply a 110-volt load from a 220-volt circuit; to supply a large 110-volt load from a 110/220-volt circuit without connecting to the neutral. In practice balance coils are not much used as the neutral can more cheaply be obtained from the transformer.

[R. A. PHILIP.]

DRAFT, MECHANICAL. — (*See also Blowers and Compressors; Chimneys; Fans; Pipes and Piping.*) Any system producing draft either by steam jets or by blowers is called a mechanical draft system. The relative advantages of mechanical draft as compared with chimney draft are: (1) The supply of air may be more readily controlled; (2) a fan permits a lower temperature of flue gases, which increases the boiler efficiency; (3) the boiler may be forced to high overloads in case of emergency; (4) the draft is uninfluenced by climatic conditions; (5) the system is low in first cost. The disadvantages of mechanical draft are: (1) danger of breakdown; (2) cost of maintenance and operation; (3) a stack or other means must be provided to carry off the flue gases wherever their discharge at low levels constitutes a public nuisance. Many plants with tall stacks are provided with mechanical-draft apparatus as a means of forcing the boilers in case of heavy overloads. Mechanical draft is also frequently used in connection with fuel economizers.

Steam Jets for producing artificial draft are simple, inexpensive and easily applied, but are very uneconomical, since they require from 6 to 11 per cent of the total steam generated (A. J. Whitham, *Trans. A.S.M.E.*, Vol. 17).

Forced Draft. — A blower system creating an excess of pressure beneath the fire is known as a forced-draft system. A single fan is commonly employed to supply a number of boilers through a system of ducts beneath the floor. The air is sometimes taken from a chamber built around the breeching, thus utilizing a part of the heat energy in the exhaust gases.

Induced Draft. — In the induced-draft system the fan is placed between the breeching and the stack. All leakage of air is inward, avoiding inconvenience when the doors are opened. This system is frequently used in plants which have high peak loads, being ordinarily installed in connection with fuel economizers. A by-pass directly from breeching to stack is usually provided for use when mechanical draft is not required or in case of accident. A double system of fans is also sometimes provided as a further insurance against accidental interruption.

POWER REQUIRED — SIZE OF FANS. — The power and size of fans required to operate either a forced-draft or induced-draft system may be roughly calculated by the method given in the article on fans. The static pressure may be roughly approximated from the data given in the article on chimneys, the figures there given for loss of draft being taken as the static pressure to be overcome. The quantity of air required per boiler horse power depends upon the quality of the coal, upon the care taken in firing and upon the efficiency of the boiler and grate (*see Boilers*).

Let R be the number of pounds of coal required per boiler-horse-power hour, W the pounds of air required per pound of coal, P the boiler horse power and $w = \frac{1.33\,B}{460 + t}$ = pounds per cubic foot of gas passing through the fan, where B is the barometric pressure in inches of mercury and t the temperature of the gas in degrees Fahrenheit; then the volume of gas passing through the fan per minute is $Q = \frac{RWP}{60\,w}$. This formula and the formula for w are strictly applicable only to the case of a forced-draft fan, but the two formulas may also be used with but a small error for an induced-draft fan, taking for t in the latter case the temperature of the discharged products of combustion (about 500° F., when no economizer is used and about 300° F. with an economizer). The size of fan and the power required to operate it will be greater for induced draft than for forced draft, since in the former case the volume of gas passing through

the fan is greater. According to Gebhardt the power required to operate a forced-draft system for a plant of 1000 boiler horse power or more, will range from 1 to 5 per cent of the plant capacity.

COSTS. — According to Gebhardt the cost of a forced-draft fan, engine and stub stack for a plant of 1000 boiler horse power or more will approximate 20 to 30 per cent of the cost of an equivalent brick chimney. The cost of a single induced fan, engine, stack, etc., will approximate 40 to 50 per cent of the cost of an equivalent brick chimney, and the double-fan outfit will be 50 to 60 per cent of that of an equivalent brick chimney. Two per cent is a liberal allowance for maintenance and depreciation of a brick or concrete chimney, while for a mechanical-draft system an allowance of from 4 to 10 per cent should be made. It costs nothing to operate a chimney, while from 1 to 5 per cent of the cost of operation of a boiler plant is chargeable to a mechanical-draft system.

[WM. KENT.]

DREDGES, ELECTRICALLY OPERATED. — (*See also Motors, Industrial Applications of.*) Electrically operated dredges are now used very generally, especially in connection with gold mining. This drive has indisputably proved its advantages over steam drive from the standpoint of both operation and economy, as individual motors can be applied to the various units of the dredging machinery, and a larger percentage of the power input can thereby be directly applied in useful work.

The standard form of dredge is of the continuous-chain, close-connected bucket type, ranging in capacity from 3 to 16 cubic feet and with a digging depth of from 40 to 60 feet. As the power is mostly obtained by transmission from some hydroelectric power system or central generating station, alternating current is generally used for driving the dredge machinery. For a modern gold-mining dredge this consists of the digger or bucket line, the winch, the high- and low-pressure pumps, the priming pump, the screen and the stacker.

Bucket Line. — The bucket line is supported on a sheet-steel or girder structure of massive construction, so as to resist the heavy strains while in operation, especially when striking rock. The speed varies from 50 feet (with from 16 to 25 buckets) to 75 feet (with from 35 to 50 buckets) per minute, depending upon the condition of the ground.

For operation and control of the digger a variable-speed induction motor is used. This is located on the lower deck and belted to the driving pulley, which is generally situated in the rear of the pilot house on the upper deck. The duty imposed upon this motor is severe, as it must operate under conditions calling for power varying from 75 per cent overload down to 25 per cent of its rated capacity. A drum-type controller for forward and reverse operation is provided, including the necessary resistance for continuous operation on any notch of the controller from one-half to full speed. The maximum starting torque is required and obtained at about the fourth point of the controller, thus leaving three points on which to bring the motor up to half speed, at which time nearly full rated torque is required. As a result of these conditions the ordinary motor designed for intermittent service cannot be successfully applied.

The raising and lowering of the bucket-line ladder is generally accomplished by a friction clutch which can be connected to the digger motor. For the larger size dredges, however, a separate motor is often provided to perform this duty.

Winch. — To keep the dredge in place and to move it about or hold it against the bank when digging, head lines are used, which are controlled from the forward end and operated by a six- or eight-drum winch driven by a variable-speed motor. The winch motor, though of smaller capacity, is of the same staunch construction as the digger motor and is equipped with a suitable controller and resistance to permit its continuous operation from one-half to full speed. It has been found advisable to equip the motors for this service with solenoid brakes, by means of which the motor can be brought to a standstill almost instantly. It is then ready for the reverse operation without the usual reversing of the motor through the controller, which is not only bad practice but may result in a burn-out due to the heavy strain on the windings.

Pumps.—The high- and low-pressure pumps for supplying water to the screens and sluices are generally connected to individual motors. Constant-speed squirrel-cage motors of compact construction and large overload capacity, with a speed of from 600 to 900 r.p.m., are usually installed for this work.

To prevent the filling up of the basin, in which the dredge floats, when digging in shallow water, it is sometimes found necessary to install a sand pump,

which carries the fine tailings from the sluice boxes to the top of the rock pile by way of the stacker.

Priming Pump. — A priming pump is required for priming the large pumps, or for supplying water on the tables during the "clean-up." It generally consists of a small centrifugal pump driven by a high-speed direct-connected squirrel-cage induction motor.

Screen. — Either a shaking or revolving screen is used to separate the gravel from the clay and permit the fine particles containing the gold to pass through on to the gold tables and sluices below. For this service a constant-speed motor is recommended, which can be placed on the upper deck and belted down to the driving pulley of the screen.

Stacker. — After screening the large rocks are carried on a belt conveyor to the end of the stacker and deposited on the spoil in the rear of the dredge. For operating this conveyor a constant speed motor is installed at the extreme end of the stacker, where it can be readily housed.

Monitor. — When a dredge is working in a high bank of hard material actual experience has demonstrated that it is advisable to lower the water level in the pit and cut the bank down with a "Giant," water being furnished by a three- or four-stage, high-pressure centrifugal pump driven by a phase-wound induction motor. The Giant is mounted on the bow of the boat, and as the dredge swings from one side of the cut to the other, the stream of water is thrown against the bank about two feet above the water level. This undermines the bank, causing the material to cave into the pond where it is brought up by the bucket line. The Giant is also used in localities where the water in the pond cannot be raised high enough to bring the bucket line near the top when the dredge is stepping ahead.

Power Required. — The sizes of motors required for driving the machinery of some dredges of different capacities are given in the following table. The proper speeds will depend on whether the motors are to be belted or direct connected to the machines which they are to drive.

SIZES OF MOTORS FOR DREDGES

Machinery to be driven	3 cu. ft. dredge, 40-ft. digging depth		5 cu. ft. dredge, 40-ft. digging depth		7 cu. ft. dredge, 40-ft. digging depth		13½ cu. ft. dredge, 40–50 ft. digging depth		16 cu. ft. dredge, 55-ft. digging depth	
	H.P.	R.p.m.	H.P.	R.p.m.	H.P.	R.p.m.	H.P.	R.p.m.	H.P.	R.p.m.
Bucket line	75	720	100	720	150	600	300	514	400	360
Winch	15	720	25	720	25	720	35	600	50	600
High-pressure pump	40	900	50	900	50	900	150	720	150	600
Low-pressure pump	25	600	25	600	25	600	75	600	100	600
Priming pump	7½	1200	7½	1200	7½	1200	25	1200	35	1200
Screen	25	900	25	900	25	600	75	600	150	600
Stacker	20	900	20	900	25	600	50	600	50	600

Voltage of Motors. — The power for operating a dredge is generally transmitted from some existing power system, and the connection between the line and the dredge is, as a rule, made by means of armored cable carried on floats. When this transmission can be economically carried out at a voltage of 2200, it is customary to provide the motors for this voltage, thus eliminating the expense of installing step-down transformers. When the transmission voltage is above 2200 volts, it is desirable to step it down to 440 volts and use motors for this voltage. When step-down transformers are required, their capacity is usually taken as two-thirds of the total horse-power load, allowing one kilowatt for each horse-power.

DYNAMOTORS. — (*See also Converters, Synchronous; Motor Generators; Transformers.*) A dynamotor is a direct-current device combining both motor and generator action in one magnetic field. It has an armature having two separate windings and two separate commutators, one at each end of the armature. Either winding may be used as the motor winding, and the other as the generator winding. Such a machine performs the same function in a direct-current circuit that a power transformer does in an alternating-current circuit, i.e., serves as a means of transforming high-voltage direct current into low-voltage direct current, or vice versa.

Performance Characteristics. — The device corresponds to two machines in which there is only one core-loss, one friction loss, one excitation loss, but two losses due to RI^2 in the two armature circuits. It is therefore more efficient than a motor-generator set, but less efficient than one machine. Since the currents in the two windings flow in opposite directions their resultant magnetic effect is zero. The machine has therefore no armature reaction (except for the slight amount due to the current to overcome the losses in the machine). It is not subject to the troubles of field distortion and bad commutation that occur in either motors or generators. It is impossible to compound a dynamotor, since any increase in field strength intended to increase the voltage of the generator would decrease the speed of the motor by the same amount and no change would result. The ratio of the two voltages is therefore fixed by the number of turns, and only varies from this by the loss due to RI drop in both windings. These two drops are additive, and therefore the regulation of such a machine is not very good.

Applications. — Dynamotors are used largely to give large currents to start other motors, or to give low voltages or a fractional voltage in a multi-voltage system for speed control. The motor of the combination may be wound for the line voltage and the generator for any fraction of the line voltage. Thus the combination supplies a large current at a low voltage, which will give a good starting torque in motors connected to it with a reasonable consumption of power. They are used as equalizers or "balancers" in three or multi-wire circuits, but are not as desirable for this work as motor-generator sets with compound-wound machines, on account of their poor regulation. They are also used to supply a low voltage for such purposes as telephone and telegraph systems and the low voltage and large currents for electrolytic work.

[W. I. Slichter.]

ELECTRICITY AND MAGNETISM, PRINCIPLES OF. — In this article are given definitions of the various electric and magnetic quantities, together with a brief statement of the fundamental principles in accord with which all electric and magnetic phenomena take place.

The following is a brief table of contents of this article:

UNITS AND QUANTITATIVE LAWS. — Three different systems of units are in use in terms of which electric and magnetic quantities are expressed. These systems are known as the c.g.s. electrostatic system, the c.g.s. electromagnetic system and the practical system (*see also Units, Practical Electric*). The various units in the practical system have been given short names which are in common use, e.g., ampere, volt, coulomb, etc. For the sake of brevity the corresponding units of the electrostatic system will be designated by these same names with the prefix "stat," and the corresponding units in the c.g.s. electromagnetic system will be designated by these same names with the prefix "ab," the latter prefix arising from the term "absolute" sometimes applied to this system.

The use of the electrostatic and electromagnetic systems of units arises from the manner in which certain of the fundamental quantitative relations, or "laws," were originally formulated. The practical system is related to the electromagnetic system, by even multiples of ten times the units in the latter, e.g., 1 volt = 10^8 abvolts, 1 ampere = 10^{-1} abamperes, 1 ohm = 10^9 abohms.

The quantitative relations given below between *electric* quantities are independent of the system of units employed provided *all the quantities involved are expressed in the same system of units*. (*See Units and Conversion Factors.*) For some of the *magnetic* quantities, certain additional practical units have been introduced which are not related to the c.g.s. electromagnetic units by multiples of 10; consequently, to avoid confusion it is best to reduce all quantities to electromagnetic units before applying any of the formulas given.

WORKING HYPOTHESIS REGARDING THE NATURE OF ELECTRICITY. — The various facts of experience described as electric and magnetic phenomena can best be coördinated by assuming at the outset the existence of electricity as an actual entity, possessing the following properties:

1. Electricity exists in two forms, which for convenience may be called "positive" and "negative" electricity. These names arise from the fact that the two kinds of electricity produce certain effects which are just the opposite of each other, and, therefore, under certain conditions the external effect of one kind of electricity may completely neutralize the effect of the other kind.

A given quantity of electricity is called an "electric charge."

2. All matter contains electricity of both kinds, even when in the neutral or "uncharged" state. An uncharged body contains in every elementary portion (or molecule) equal quantities of positive and negative electricity, so thoroughly

"mixed" that no external effects are produced, unless the two kinds of electricity are constrained to take up a definite position or to move in a definite manner.

3. A body or portion of a body can be charged with electricity of either kind either by adding to it electricity of that kind or by taking away from it electricity of the other kind. In general only the *surface* of a body can be charged, i.e., the excess or deficit of charge exists only at the surface of separation between this body and some other body, the interior elements of the body containing, as in the neutral state, equal amounts of electricity of opposite kinds.

4. It is impossible to charge a body with electricity of one sign without producing on the same or on some other body an equal charge of the opposite sign.

5. Forces can be produced on the electricity in a body by various external agents, without necessarily producing a force on the body as a whole. When such forces are produced the two kinds of electricity are either displaced relatively to each other or are constrained to move through the body in opposite directions. This displacement or motion is always opposed by forces set up within the body itself. The opposing forces are of two kinds, (1) a force analogous to the opposing force set up in an elastic body when it is stretched or compressed, and (2) a force analogous to the resisting force due to mechanical friction produced when one body moves over another.

6. When the electricity in a body is acted upon by an external force, but cannot escape from that body to another, this force is transmitted to the body itself.

7. Electricity possesses inertia, just as ordinary matter possesses inertia; i.e., a force is required to change the motion of a charge of electricity just as a force is required to change the motion of a portion of matter. The "effective" inertia of a given quantity of electricity depends upon the path over which it is caused to move and upon the nature of the surrounding bodies (*see Electron Theory*).

Unit of Charge or Quantity of Electricity. — The unit of electric charge or quantity of electricity in the practical system of units is called the coulomb. For the relation between the coulomb, statcoulomb, abcoulomb, and other units of quantity see *Units and Conversion Factors*.

ELECTRIC FIELDS OF FORCE. — In any portion of a substance in which the electricity is acted upon by a force tending to move it, there is said to be an "electric field of force," or briefly an "electric field." An electric field is also said to exist in any region of free space where a charge, if placed there, would have a force exerted upon it tending to move it.

Intensity of an Electric Field (F). — The "intensity" of an electric field at any point is defined as the force per unit positive charge exerted on a charge at this point by the agent or agents producing the field i.e., by the agent or agents tending to move the charge. The direction of the field intensity, or the direction of the field, is defined as the direction of the force acting on a *positive* charge at this point. A positive charge then moves or tends to move in the direction of the field and a negative charge moves or tends to move in the opposite direction.

Units of Electric Field Intensity. — The unit of electric field intensity has not been given any special name, but since it is of the same nature as electromotive force per unit distance the intensity at any point may be conveniently expressed as so many volts, abvolts or statvolts *per centimeter* or *per inch;* see *Units and Conversion Factors*. Hence electric field intensity is frequently called the potential or voltage "gradient."

Lines of Electric Force. — Lines of Electric Intensity. — A line drawn

with the direction of the field at that point is called a "line of electric force." A line of force is usually a curved line, though in certain special cases it may be straight. Any number of such lines may be drawn in an electric field, but no two of these lines can intersect. The density of these lines, i.e., the number drawn through unit area perpendicular to their direction, may be chosen arbitrarily to represent the value of the field intensity at this area, and when so drawn are preferably called "lines of electric intensity," as distinguished from flux lines and stream lines defined below. The term "lines of force," however, is frequently used to designate any one of these three sets of lines, but this loose use of the term is liable at times to lead to much confusion. The term "line of electric force" will be used in this article to designate merely the *direction* of the field at any point; in any statement involving the *density* of these lines the proper one of the other terms will be employed.

Electric Equipotential Surfaces. — A surface drawn in an electric field in such a manner that it is perpendicular at each point to the line of force through that point is called an "electric equipotential surface." The electric intensity has no component along such a surface, and therefore no work is required to move a charge from one point to another over any path in such a surface.

ELECTROMOTIVE FORCE (E). — The work done by the field intensity F in moving unit positive charge around any *closed* path or circuit (Fig. 1) in an electric field is defined as the "electromotive force," abbreviated "e.m.f.," acting around this path. Electromotive force is not a force in the mechanical sense but is *work per unit charge*. The relation between electromotive force E and field intensity F is analogous to that between work and mechanical force viz.,

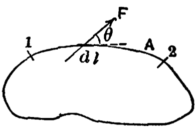

Fig. 1.

$$E = \int (F \cos \theta)\, dl, \qquad (1)$$

where dl represents an elementary length of the path, $(F \cos \theta)$ the *component* of the field intensity along dl and $\int$ represents the integral around this closed path. When the field intensity has the same value F at every point of a path and coincides in direction with the path at every point, the electromotive force acting around the closed loop is

$$E = Fl \qquad (1a)$$

where l is the total length of the path.

Units of Electromotive Force. — The practical unit of electromotive force is the volt; see *Units, Practical Electrical.* See also *Units and Conversion Factors* for the other units and their interrelations.

Sources of Electromotive Force. — The primary sources of e.m.f. are (1) two dissimilar bodies in contact (*see Batteries; Electrochemistry, Principles of*) and (2) a varying magnetic flux linking the circuit (*see the articles on Generators; Transformers, etc.*). The e.m.f. is said to be "located" at the surface of contact in the case of a "contact" e.m.f., or in that portion of the circuit which is linked by the varying magnetic flux in the case of an "induced" e.m.f., for experience shows that the value of the work integral, equation (1), around any circuit passing through a given surface of contact or linking a given varying flux is always the same, irrespective of the shape of the circuit and of the nature of substance through which the path passes, provided there are no other sources of e.m.f. in this path. Contact e.m.f.'s are usually extremely

small (of the order of 0.001 volt) except in the case of metallic substances in contact with electrolytes, in which case they may amount to several volts, see *Batteries; Electrochemistry, Principles of.* E.m.f.'s of 500,000 volts or more can be produced by a varying magnetic flux.

Direction of an Electromotive Force. — The direction of the e.m.f. *in* any portion of a circuit is taken as the direction in which a positive charge would be forced *around* a circuit containing only this one source of e.m.f. A closed circuit may contain several sources of e.m.f.; in this case the resultant e.m.f. acting around in the circuit is the *algebraic* sum of all these e.m.f's, the e.m.f.'s acting around the circuit in one direction being taken as positive and those acting around the circuit in the opposite direction being taken as negative. Those e.m.f.'s which act in the opposite direction to the resultant e.m.f. are called "back" or "counter" e.m.f.'s.

A convenient symbol for a source of constant e.m.f. is shown in Fig. 2; the long light line represents the positive terminal and the short heavy line the

Fig. 2.

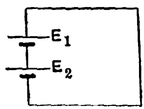

Fig. 3.

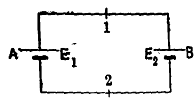

Fig. 4.

negative terminal. Fig. 3 shows two e.m.f.'s acting around a circuit in the same direction, and Fig. 4 shows two e.m.f.'s acting around the circuit in opposite directions. In the first case the resultant e.m.f. is $E_1 + E_2$ and the two e.m.f.'s are said to be "in series," and in the second case the resultant e.m.f. acting in the right-handed direction around the circuit is $E_1 - E_2$ and the two e.m.f.'s are said to be "in opposition." When E_2 is less than E_1 then E_2 is a back or counter e.m.f.

DIFFERENCE OF ELECTRIC POTENTIAL (V). — Consider a portion of a path A between any two points 1 and 2 in an electric field (Fig. 1). The total work done on unit charge, *by the e.m.f.'s external to this portion of the path* when unit charge moves from 1 to 2, is called the "drop of electric potential" from 1 to 2. The term "difference" of electric potential is also commonly used to designate this quantity; the term "drop" is preferable since it signifies the direction of the difference. Electric potential drop is of the same nature as electromotive force and is expressed in the same units. It is frequently abbreviated "p.d." Potential drop may be due either (1) to a "back" electromotive force, analogous to the back pressure of a pump, or (2) to an opposing force analogous to that due to the resistance of a pipe to the flow of water.

Let the path from 1 to 2 be in the direction of the line of force from 1 to 2, let E_{12} be an e.m.f. whose source is between 1 and 2 and whose direction is from 1 to 2, then the general expression for the potential drop from 1 to 2 is

$$V_{12} = \int_1^2 F\,dl - E_{12}. \tag{2}$$

The first term represents the "resistance" drop and $-E_{12} = E_{21}$ represents the "back" pressure. If the field intensity along the path from 1 to 2 is negligible, then $V_{12} = -E_{12}$; hence an e.m.f. in a given direction is equivalent to a negative

(2) with equation (1) it is evident that the total drop of potential around a *closed* circuit is always zero. This relation is conveniently expressed by the formula

$$\Sigma V = 0 \qquad (3)$$

which holds for every closed path or circuit. This is one way of stating Kirchhoff's second "law."

Voltage and Voltage Gradient. — The term "voltage" is commonly used for either an e.m.f. or a potential difference, particularly when these quantities are expressed in volts. Since from equation (2) the field intensity F is equal in volts to the drop in voltage per unit length the electric field intensity is also frequently called the voltage "gradient."

Positive and Negative Terminals. — That terminal of a device which is at the higher potential is called the positive terminal, the other terminal being called the negative terminal. The drop of potential is *always* from the positive to the negative terminal, irrespective of the direction of flow of electricity through the device.

FLOW OF ELECTRICITY. — Whenever an electric field is set up in a substance by any means whatever a displacement of the electricity in that substance always takes place, the nature of the displacement depending upon the nature of the substance. In every case the positive electricity within the substance is displaced in the direction of the field intensity and the negative electricity in the opposite direction, until an opposing force of some kind is set up which just balances the forces due to the impressed field.

Conductors and Insulators or Dielectrics. — A substance in which a *constant* electric field is always accompanied by a *continuous* displacement or *flow* of electricity through the substance is called an "electric conductor;" when there is no flow of electricity through a conductor the field within the conductor is *always* zero. Every substance is a conductor of electricity, at least to a slight extent, but some substances are far better conductors than others. A substance in which a constant electric field produces only a relatively small continuous flow of electricity is called an "electric insulator" or "dielectric." A *perfect* dielectric may be defined as a substance through which it is impossible to set up a continuous flow of electricity; no such substance exists but very poor conductors are approximately such. Free space may be considered a perfect dielectric, but free space differs from a substance in that it does not contain electricity.

Metals are the best conductors, carbon and most moist substances are fair conductors; dry non-metallic bodies such as air and other gases (at normal pressure), porcelain, glass, rubber, and dry paper are very good insulators.

A wire covered with an insulating substance or supported on insulating substances is said to be "insulated," even though its ends are connected to a source of e.m.f.

Electric Current (I). — The displacement of the electricity within a substance cannot be measured directly, but only in terms of some effect produced thereby. Two effects which always occur when a displacement of electricity is produced are (1) a magnetic field is established around the path along which the displacement takes place (but disappears when the electricity comes to rest) and (2) heat is developed in the path of the displacement. The magnetic field produced by a displacement or flow of electricity is usually taken as the measure of the *rate* of flow, i.e., of the quantity of electricity displaced per unit time through a surface perpendicular to the direction of the displacement. This rate of flow is called the "intensity" of the electric current, or simply the "electric current," and is usually represented by the symbol I.

Direction of the Electric Current. — A flow of positive electricity in one direction is equivalent magnetically to a flow of an equal amount of negative electricity in the opposite direction; hence the total flow along a given path is the sum of the positive electricity displaced per unit time in one direction past a point in this path plus the negative electricity displaced per unit time past this point in the opposite direction. The "direction" of the electric current is taken as the direction in which the positive electricity is displaced, and is, therefore, the same as the direction of the field intensity.

Current due to Varying Electric Field. — When the electric field in any substance is *varying*, the total magnetic effect produced is found to depend not only upon the rate of displacement of the electricity within the substance, but also upon the *rate of change* of the electric field. In fact, a magnetic field is produced around a path in *free space* along which the intensity of the electric field is varying, see *Waves, Electromagnetic*. In dealing with varying electric fields it is found convenient to consider the variation of the field intensity as equivalent to an actual flow of electricity, and to take as the total *equivalent* electric current the flow of electricity which would produce the same magnetic field as that actually observed; the *actual* flow of electricity is then in general less than this equivalent current, but the difference is negligible except in substances which are good insulators.

Units of Electric Current. — The practical unit of electric current is the ampere; see *Units, Practical Electrical*. For the relation between this unit and the statampere and abampere see *Units and Conversion Factors*.

Continuity of an Electric Current. — When a varying electric field is considered as equivalent to an electric current, it is found that the total equivalent current coming up to any point or surface in any network of circuits, no matter how complicated, is *always* equal to the total current leaving that point or surface, irrespective of the nature of the substances through which the currents are established and irrespective of whether the currents are constant or are varying. For example, in Fig. 5,

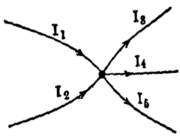

Fig. 5.

$$I_1 + I_2 = I_3 + I_4 + I_5. \tag{4}$$

Or, calling the currents coming up to any point positive, and the currents leaving that point negative, the *algebraic* sum of all the currents at any point in a network of circuits is always zero. This fundamental principle is conveniently expressed by the formula

$$\Sigma I = 0 \tag{5}$$

which holds at every junction point both for variable and for continuous currents. This is Kirchhoff's first "law."

Stream Lines of Electric Current. — Current Density (σ). — As a consequence of the continuity of an electric current, the total current in any substance of any size or shape may be looked upon as made up of a number of small streams of electricity flowing side by side, the strength (quantity of electricity per second) of each stream being constant throughout its length. If the cross-section of each stream at any point is so chosen that each stream represents unit current (unit quantity per second), then the number of these streams crossing unit area of a surface perpendicular to their direction will be equal to the current per unit area of this surface, or to the "current density" at this surface. Each such stream may be represented graphically by a line coinciding with its axis; such lines are called "stream lines." When the stream

the current at this point and the number of these lines per unit area perpendicular to their direction is equal to the current density at this point.

In the case of an insulated wire the stream lines are parallel to the axis of the wire, except in the immediate vicinity of its ends; this non-uniformity at the ends in the case of a long wire is negligible. The stream lines in an ordinary wire may also, in most practical cases, be considered as all coinciding, and the wire may, therefore, be treated as a geometrical line as regards *external* effects. However, in the case of a short rod or strip (such as an ammeter shunt) connected in the circuit by wires attached to its ends, the stream lines are not in general parallel but diverge from one terminal and converge toward the other.

Continuous, Direct, Pulsating, Alternating and Oscillatory Currents.— A "continuous" electric current is defined as a current which does not vary with time. A "direct" current is a current which is always in the same direction but may vary or pulsate in value. The term "direct current" is ordinarily used to designate either a continuous current or a current which varies or pulsates only by an inappreciable amount, such as the current from a battery or direct-current generator (q.v.). A "pulsating" current is a direct current which pulsates by an appreciable amount, such as the current from a rectifier (q.v.). An "alternating" current is a current which reverses in direction, being first positive and then negative, but alternates between *constant* maximum positive and negative values; see article on *Alternating Currents*. An "oscillatory" current is a current which reverses in direction, oscillating between positive and negative values which either decrease or increase with time.

Conduction Current and Displacement Current. — Experience shows that when an electric field is established in any substance, the total equivalent electric current set up depends (1) upon the value of the field intensity, (2) upon the rate of change of the field intensity, and (3) upon the nature of the substance in which the field is established. The current density σ at any point at any instant may in general be expressed by the relation

$$\sigma = \gamma F + \frac{1}{4\pi}\frac{d}{dt}(kF), \tag{6}$$

where F is the field intensity, γ and k are coefficients depending upon the chemical nature and physical condition of the substance at the point in question, and $\frac{d}{dt}$ means the rate of change with respect to time, the factor 4π arising from the historical definition of the quantity k, see below. The total current may then be considered as the sum of two components having respectively the densities

$$\sigma_1 = \gamma F \quad \text{and} \quad \sigma_2 = \frac{1}{4\pi}\frac{d}{dt}(kF). \tag{6a}$$

The first of these components (σ_1) is called the "conduction" current, and the second (σ_2) is commonly called the "displacement" current. The term "displacement" current, however, is somewhat a misnomer, for both components of the total current are probably due, in part at least, to a displacement of electricity; whereas a displacement current is set up by a varying electric field in a *free space*, although there is probably no electricity in free space to be displaced. The conduction current is the only appreciable component in substances usually classed as conductors, and the displacement current is appreciable only in substances ordinarily classed as dielectrics. The conduction current in a dielectric is usually small, though measurable; it is frequently called the "leakage" current. When the electric field in a dielectric is rapidly varying the displacement current may be many times greater than the conduction or leakage current through the dielectric.

Conductivity (γ) and Resistivity (ρ). — The quotient of the density σ_1 of the conduction current by the field intensity F, i.e., the coefficient γ in the expression $\sigma_1 = \gamma F$ is called the "conductivity" of the substance at the point in question. Since in an ordinary conductor the displacement current is inappreciable, the conductivity of an ordinary conductor is also equal to the density of the total current divided by the field intensity, i.e., for a conductor

$$\sigma = \gamma F, \tag{7}$$

where σ represents the density of the total current. Experience shows that for a given conductor at constant temperature (and also at constant pressure in case of a gas) this coefficient γ is a constant irrespective of the strength, distribution or time variation of the current. The value of γ for a dielectric, however, is not in general a constant but depends upon the time variation of the field intensity; see below under *Capacity and Condensers*.

The above relation between σ and F may also be written

$$F = \rho\sigma, \tag{7a}$$

where ρ is the reciprocal of the conductivity γ. The constant ρ is called the "resistivity" or "specific resistance" of the substance. Values of γ and ρ for various conductors are given in the article on *Resistance and Conductance*, and also the methods of measuring these quantities. The values of γ and ρ for some of the more common insulating materials are given in the article on *Insulating Materials, Properties of*. For the units of conductivity and resistivity see *Units and Conversion Factors* and also the next two paragraphs.

Conductance (g) and Resistance (r). — To cause a *continuous* current I to flow through a given conductor in which there is no source of e.m.f. a difference of potential must be established by some external agent between the ends of the conductor. Let V be the potential drop established through the conductor, from any point 1 to any other point 2, then the quotient

$$g = \frac{I}{V} \tag{8}$$

is defined as the "conductance*" from 1 to 2, and the quotient

$$r = \frac{V}{I} \tag{8a}$$

is defined as the "resistance*" from 1 to 2. Conductance is the reciprocal of resistance and vice versa. The practical unit of resistance is called the ohm, and the practical unit of conductance is called the mho; see *Units and Conversion Factors*.

It should be carefully noted that the definitions expressed by equations (8) and (8a) hold only when there is no e.m.f. in the portion of the circuit under consideration; this condition is realized only when the current remains constant in value (i.e., a *continuous* current) and the conductor is of uniform material and at constant temperature throughout. Also, the definition is meaningless unless the same current flows through each cross-section of the conductor and the drop of potential is the same between all points in the two end surfaces; i.e., the end surfaces must be equipotential surfaces.

Factors Upon Which Conductance and Resistance Depend. — The resistance or conductance of a given portion of a conductor included between

* Frequently called the "ohmic" or "d-c." conductance and resistance respectively to distinguish these quantities from the "effective" or "a-c." conductance and resistance; see article on *Resistance and Conductance*.

two equipotential surfaces and bounded laterally by a surface through which no stream line passes, depends upon (*a*) the conductivity of the conductor (*b*) the dimensions of this portion of the conductor, and (*c*) the distribution of the stream lines over each cross-section perpendicular to them. Consider the case of a straight wire or bar over the cross-section of which the current is uniformly distributed. Let l be the length of the bar, A its cross-section and ρ its resistivity. Then from equation (2) the drop of potential along the length l is $V = Fl$; from equation (7a) $F = \rho\sigma$; therefore $V = \rho\sigma l$. The total current $I = \sigma A$; whence the resistance and conductance are

$$r = \rho\frac{l}{A} \quad \text{and} \quad g = \gamma\frac{A}{l}. \tag{9}$$

Hence, the conductivity of a substance is equal to the conductance, and the resistivity is equal to the resistance, of a unit cube of this substance when the current through this cube is parallel to four edges of the cube and is uniformly distributed over the section at right angles to these four edges. Hence conductivity is frequently expressed as mhos per centimeter cube or inch cube; see *Resistance and Conductance; Units and Conversion Factors.*

Equation (9) is applicable only to a conductor in which the stream lines are uniformly distributed and parallel to each other, such as in insulated wires carrying continuous or comparatively slowly varying currents. When the stream lines are not parallel to each other, let dl represent an elementary length along any stream line and σ the current density at dl; then taking the integral along the stream line from one end surface to the other, the resistance is

$$r = \frac{\rho\int\sigma\,dl}{I} \tag{9a}$$

where I is the total current. The calculation of the value of σ at each point along the line from one surface to the other is difficult except in certain special cases of symmetry; see however, equation (22) below.

Ohm's Law and Resistance Drop. — From the relations noted above it is evident that, in a conductor (*a*) which remains at constant temperature, (*b*) in which there is no internal e.m.f., and (*c*) in which the distribution of stream lines remains unaltered *the quotient of the voltage by the current is a constant.* This relation is known as Ohm's Law; it holds only when the three conditions specified above are fulfilled.

The above relation may also be written $V = rI$ which is merely another form of equation (2); i.e., if r is the resistance between any two points 1 and 2 in an electric circuit in which the current is I, then the integral of the electric field intensity along the path from 1 to 2 is equal to rI. This drop of potential due solely to resistance between 1 and 2 is called the "resistance drop" from 1 to 2, and is always in the direction of the current. When there is an e.m.f. in the circuit between 1 and 2 and the distribution of current remains the same,* the total drop from 1 to 2, from equation (2), is

$$V_{12} = rI_{12} - E_{12}, \tag{10}$$

the subscripts indicating the directions of the various quantities. Equation (10) is sometimes referred to as the "modified" Ohm's law.

* In general, the distribution of current depends upon the time variation of the voltage; see article on *Skin Effect.*

Terminal and Impressed Voltages. — The application of this equation is best shown by considering a simple circuit containing a generator and a motor or other receiving device, Fig. 6. Let I be the current in this circuit, let R_g be the internal resistance of the generator, R_m the internal resistance of the motor and R_l the total resistance of the "line" or connecting wires, let E_g be the e.m.f. developed by the generator and E_m the back e.m.f. developed by the motor, and let V_g be the terminal voltage of the generator and V_m the terminal voltage of the motor. Through the generator the current flows from the − to the + terminal, the e.m.f. is from the − to the + terminal, and the drop of potential is from the + to the − terminal. Hence

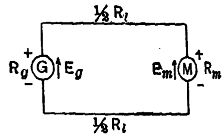

Fig. 6.

$$V_g = E_g - R_g I, \tag{10a}$$

i.e., the terminal voltage is less than the generator e.m.f. by an amount equal to the resistance drop in the armature. Through the motor the current flows from the + to the − terminal, the e.m.f. is from the − to the + terminal, and the drop of potential is from the + to the − terminal. Hence

$$V_m = E_m + R_m I, \tag{10b}$$

i.e., the terminal voltage is greater than the back e.m.f. of the motor by an amount equal to the resistance drop through the motor.

The terminal voltage of the motor is less than that of the generator by an amount equal to the resistance drop in the line, i.e.,

$$V_m = V_g - R_l I. \tag{10c}$$

The expression "impressed" electromotive force is also used to designate the rise of potential from the negative to the positive terminal of any receiving device, whether it be a motor, bank of lamps, or any "straight" resistance, i.e., a resistance containing no source of electromotive force.

Series Circuits. — When several conductors are connected end to end so that the *same current* flows through each of them (Fig. 7), they are said to be connected "in series." Let I_{12} be the current in each conductor in the direction from 1 to 2, let R', R'', R''', etc., be the resistances of the various conductors and E'_{12}, E''_{12}, E'''_{12}, etc., be the e.m.f.'s in the circuit between 1 and 2 in the direction from 1 to 2. Then the potential drop from 1 to 2 is

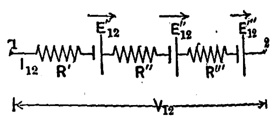

Fig. 7.

$$V_{12} = R'I_{12} - E'_{12} + R''I_{12} - E''_{12} + R'''I_{12} - E'''_{12}, \text{ etc.}$$

Therefore, the resistances between the points 1 and 2 are equivalent to a single resistance

$$R = R' + R'' + R''', \text{ etc.,} \tag{11}$$

and the e.m.f.'s between the points 1 and 2 are equivalent to a single e.m.f.

$$E_{12} = E'_{12} + E''_{12} + E'''_{12}, \text{ etc.} \tag{11a}$$

The equivalent conductance of several conductances G', G'', G''', etc., in series *when there are no e.m.f.'s in the path*, is G where

$$\frac{1}{G} = \frac{1}{G'} + \frac{1}{G''} + \frac{1}{G'''} + \dots \tag{11b}$$

Parallel Circuits. — When several conductors are connected to two common junction points so that the *same potential drop* is established through each (Fig. 8), they are said to be "in parallel." Let the currents, e.m.f.'s and resistances be as designated in the figure. Then from equation (5)

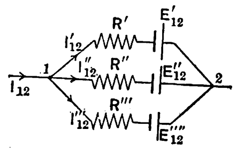

Fig. 8.

$$I_{12} = I'_{12} + I''_{12} + I'''_{12} + \text{etc.}$$

and from equation (10a)

$$V_{12} = R'I'_{12} - E'_{12} = R''I''_{12} - E''_{12} = R'''I'''_{12} - E'''_{12} = \text{etc.},$$

from which relations the currents in the individual branches may be calculated.

When there are no e.m.f.'s in the various branches, the combined resistance of the several branches from 1 to 2 is R where

$$\frac{1}{R} = \frac{1}{R'} + \frac{1}{R''} + \frac{1}{R'''} + \dots, \tag{12}$$

and the combined conductance is

$$G = G' + G'' + G''' + \dots, \tag{12a}$$

where G_1, G_2, G_3, etc., are the individual conductances.

Two Parallel Circuits. — In the special case of two conductors in parallel, and no e.m.f. in either, the combined resistance is

$$R = \frac{R_1 R_2}{R_1 + R_2}. \tag{12b}$$

Series-parallel Circuits. — When a circuit is made up of several conductors some of which are in series and some in parallel, it is called a "series-parallel" circuit. The total resistance or conductance of such a circuit can be calculated from the constants of the several branches by applying successively the formulas for series and for parallel circuits.

Kirchhoff's Network Laws. — The relations given above for conductors in series and in parallel are special cases of two general laws already stated, namely:

1. The algebraic sum of the currents coming up to any junction in a network of conductors is always zero (equation 5).
2. The algebraic sum of the potential drops around any closed loop in a network of conductors is always zero (equation 3).

These two laws are known as Kirchhoff's Laws, from the name of the scientist who first clearly enunciated them. By making use of them one can always predetermine (*a*) the current in each branch of a network when the resistance of each branch and the e.m.f. in each branch are known, or (*b*) the e.m.f. in each branch when the current in each branch and the resistance of each branch are known.

It should be carefully borne in mind in applying these laws that a current leaving a point is equivalent to a negative current *entering* that point, and that

an e.m.f. in any chosen direction is equivalent to a *rise* of potential in that direction. In working out any problem concerning a network of circuits it is convenient to make a diagram of the network and to place on each branch in this diagram a number or symbol to represent the value of the current in this branch and an arrow or subscripts to indicate the direction of the current represented by this number or symbol, and wherever there is an e.m.f. to place a number or symbol to represent the value of this e.m.f. and an arrow or subscripts to indicate its direction. Then at any junction point those currents represented by arrows pointing toward the point are to be considered positive (say) and those represented by arrows pointing away from the point are to be considered negative; and for any closed loop those currents and e.m.f.'s represented by arrows pointing around the loop in the clockwise direction (say) are to be considered positive and those pointing around the loop in the counter-clockwise direction are to be considered negative. With this understanding, these laws may be written

$$\Sigma I = 0 \text{ at every point,} \tag{13a}$$

$$\Sigma E = \Sigma rI \text{ for every closed loop,} \tag{13b}$$

where I, r and E represent the current, the resistance and the e.m.f. respectively in each branch of the loop, and the symbol Σ indicates the algebraic sum of the quantities following it.

These equations enable one to write down a set of simultaneous equations for the given network, but it will be found that at least one of the current equations may be derived directly from the other current equations, and that at least one of the potential equations may be derived from the other potential equations. That is, the number of independent equations of each form will be one less than the number which it is possible to write down. It should also be noted that it is frequently unnecessary to write down formally all the possible independent equations; many of the simpler problems can be solved by writing down two independent expressions for the potential drop between each pair of points and equating these two expressions.*

When the currents and e.m.f.'s are *varying*, the first law applies to the total current (conduction and displacement current), but the second law in the form given in (13b) applies only to closed loops of conduction current; in both cases the instantaneous values of the currents and e.m.f.'s must be taken when the quantities are varying.

ELECTRIC ENERGY AND POWER. — From the definition of potential drop it follows that the total work done by the external agents in forcing Q units of electricity from any point 1 in a circuit to any point 2 is $W = VQ$. From the definition of electric current the quantity of electricity carried from 1 to 2 when the current I is established from 1 to 2 is $Q = It$, where t is the time during which the current exists. Hence when a current I is established through any device for a time t by an impressed voltage V, the energy input to this device is

$$W = VIt \tag{14}$$

and the power input, i.e., energy input per unit time, is

$$P = VI. \tag{15}$$

When V and I are expressed in volts and amperes respectively the power input is in watts; if t is in seconds, the energy input is in joules or watt-seconds. When V and I are in statvolts and statamperes respectively, or in abvolts and abam-

* The application of these laws to the solution of complicated network problems is

peres respectively, the power input is in ergs per second, if t is in seconds the energy input is in ergs. See *Units and Conversion Factors.*

Applying the above relations to the simple circuit shown in Fig. 6 containing a generator and a motor (armature windings only are considered), the power *input* to the motor armature is

$$P_i = E_m I + R_m I^2, \tag{15a}$$

the power *output* of the generator armature is

$$P_0 = E_g I - R_g I^2 \tag{15b}$$

and the power lost in the line is

$$P_l = R_l I^2.$$

The term $R_g I^2$ represents the power lost in heating the armature winding of the generator due to its resistance, and the term $R_m I^2$ represents the power dissipated as heat in the armature winding of the motor. The net electric input to the generator armature is $E_g I$ and the gross mechanical output of the motor armature is $E_m I$. The gross mechanical input to the generator is greater than $E_g I$ and the net mechanical output of the motor is less than $E_m I$ by an amount equal to the friction and "core-loss" in the respective machines; see *Generators and Motors.*

Joule's Law.—That portion of the power input to any device which is equal to the product of the resistance of the conductors forming the winding of the device by the square of the current through this winding is always converted into heat. That is, when a current I flows through a resistance r heat is always "dissipated" in this resistance, and the rate of dissipation is

$$P_h = rI^2. \tag{15c}$$

This experimental fact is known as "Joule's Law." This law applies directly only to continuous or non-varying currents. The relation $P_h = rI^2$ is, however, used as the basis for defining the "effective" resistance of a conductor to an alternating current (q.v.).

DIELECTRIC FLUX (ψ) AND DIELECTRIC FLUX DENSITY (D).—As noted above the displacement current through a dielectric at any point depends upon the rate of change of the electric field intensity and upon the nature of the dielectric, and the density of this displacement current at any point may be expressed by the relation

$$\sigma_2 = \frac{1}{4\pi}\frac{d}{dt}(kF), \tag{16}$$

where F is the field intensity and k a coefficient depending upon the nature of the dielectric. The coefficient k in this expression is the so-called dielectric coefficient or dielectric constant.

The quantity kF, whose rate of change is equal to 4π times the density of the displacement current, is called the "dielectric flux density," and may be represented by the symbol D. Then

$$D = kF. \tag{17}$$

The direction of the dielectric flux density is arbitrarily chosen to be the same as that of the electric field intensity F. Through any surface of area A at each point of which the dielectric flux density has a constant value D and is perpendicular to that surface, there is said to exist a "dielectric flux" equal to DA. The total dielectric flux through a surface may be represented by the symbol ψ.

In general, the total dielectric flux through any surface perpendicular at each point to the direction of the field intensity at that point (i.e., through an equipotential surface) is

$$\psi = \int D\, ds, \tag{18}$$

where ds represents any elementary area of this surface and D the flux density per unit area at ds, and $\int$ represents the sum of all the products $D\,ds$ for that surface. The total displacement current through this surface is then

$$i = \frac{1}{4\pi}\frac{d\psi}{dt}. \tag{19}$$

Lines of Dielectric Flux. — The electrostatic flux through any surface may be represented by lines drawn in the same direction as the lines of electric intensity, but of such a density that *their number per unit area* perpendicular to their direction at any point *is equal* to the *dielectric flux density* at this point. The number of these lines cutting any surface is then equal to the total dielectric flux through this surface. The ratio of the number of flux lines through any surface to the number of lines of electric intensity through that surface is equal to the dielectric coefficient of the substance in which the field exists.

ELECTRIC CHARGE (Q) AND DIELECTRIC FLUX (ψ). — *Within* any substance of uniform structure throughout the dielectric flux lines are continuous lines, i.e., the number of these lines coming up to one side of a surface *within* such a substance is equal to the number of these lines leaving the other side of that surface. Experience shows that it is impossible to produce an appreciable dielectric flux in those substances ordinarily classed as conductors; *hence dielectric flux lines cannot pass through a good conductor*, but terminate at its surface. Every dielectric is a conductor to at least a slight extent, and on account of this fact the dielectric flux lines coming up through one dielectric to the surface of contact between this dielectric and another do not all pass through the second dielectric, but some of them terminate at this surface.

Experience shows that to establish an electric field in the dielectric around a conductor, electricity must be *conducted through the conductor* to the surface of contact between the conductor and the dielectric. For example, consider a good conductor in contact with a perfect dielectric, Fig. 9; a momentary conduction current must flow through the conductor along the stream lines of the conduction current, represented by the dotted lines. While the field is being established (and therefore varying) a displacement current is set up in the dielectric requiring an equal conduction current in

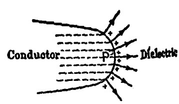

Fig. 9.

the conductor, and consequently $\frac{1}{4\pi}$ times the rate of change of the dielectric flux (ψ) established in the dielectric must be equal to the conduction current (i) flowing up to this surface through the conductor, i.e.,

$$\frac{1}{4\pi}\frac{d\psi}{dt} = i,$$

or

$$\psi = 4\pi \int i\, dt = 4\pi Q, \tag{20}$$

where Q is the quantity of electricity (current multiplied by time) conducted through the conductor to this surface.

This relation is a general one, viz., the total dielectric flux from any area A in the surface of a *conductor* is equal to 4π times the total charge on this area. Hence every flux line originates at a positively charged conducting surface and terminates at a negatively charged conducting surface, 4π of these lines connecting each unit positive charge to each unit negative charge.

The quantity of electricity conducted through a conductor when a momentary current is established through it can be readily measured by means of a ballistic galvanometer (*see Galvanometers*) and consequently the dielectric flux (equal to $4\pi Q$) may be readily determined.

Units of Dielectric Flux. — Dielectric flux may be expressed in the same unit as electric charge, viz., coulombs, statcoulcombs or abcoulombs; see *Units and Conversion Factors*.

Surface Density of Charge (σ_c) and Dielectric Flux Density (D). — When there is no current in a conductor there can be no electric field within it, see equation (7), and therefore *the surface of a conductor in which no current is flowing is always an equipotential surface.* Hence the lines of electrostatic intensity, in the surrounding dielectric, and therefore the dielectric flux lines also, must leave or enter this surface in a direction perpendicular to it. The dielectric flux density in the dielectric just outside a conducting surface in which there is no electric current is perpendicular to this surface and is

$$D = 4\pi\sigma_c, \tag{20a}$$

where σ_c is the charge per unit area of the surface at this point, or the "surface density" of the charge.

Dielectric Flux Density Due to a Number of Charged Conductors. — It can be shown that when any number of charged conductors are surrounded by a *uniform* dielectric, the dielectric flux density at any point in the field may be expressed by considering each elementary surface having a charge q as producing at any point P at a distance r from q a flux density equal to q/r^2, in the direction of the line from q to P when q is positive and in the direction of the line from P to q when q is negative. The total flux density at P due to all the charges is then the *vector summation*

$$D = \sum \frac{q}{r^2}. \tag{20b}$$

Dielectric Flux Density at any Point due to a Uniformly Charged Wire of Circular Cross Section and Infinite Length. — Let q be the charge per unit length, K the dielectric coefficient of the surrounding dielectric, assumed uniform, and r the perpendicular distance from the center of the wire to any point P, then the dielectric flux density at P due to this wire is

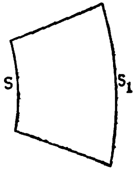
$$D = \frac{2q}{r} \tag{20c}$$

The resultant dielectric flux density at any point due to any number of *uniformly* charged wires is the vector sum of the flux densities due to each separately. However, when two or more wires are close together the distribution of charge on them is not uniform,* but when the wires are more than 10

* The distribution can be calculated readily in the case of two parallel wires; see Pender and Osborne, *Elec. World*, *1910*, *Vol. 56*, *p. 667*.

diameters apart the error introduced by the assumption of uniform charge is practically negligible.

ELECTROSTATIC CAPACITY (C) AND CONDENSERS.—To establish a given dielectric flux ψ through a given dielectric a certain difference of electric potential is always required. Consider any portion of an electric field (Fig. 10) between the two equipotential surfaces S and S_1 bounded laterally by a surface tangent at each point to the flux line through that point. Let V be the drop of potential from S to S_1, and let ψ be the dielectric flux through this region. When there is no source of e.m.f. between S and S_1 the quotient



$$C = \frac{\psi}{4\pi V} \tag{21}$$

Fig. 10.

is defined as the "electrostatic capacity" of this portion of the field. Compare with the definition of conductance, equation (8).

When the equipotential surfaces S and S_1 are the surfaces of two conductors, the two conductors and the dielectric between them are said to form an "electric condenser." Practical forms of condensers are described in the article on *Condensers, Electric*. When all the flux lines from one conductor end on the second conductor (e.g., when they are given equal and opposite charges by connecting them respectively to the two terminals of a source of e.m.f.), then the flux from one to the other is equal to $4\pi Q$ where Q is the numerical value of the total charge on either conductor. The capacity of the condenser may then be written

$$C = \frac{Q}{V}. \tag{21a}$$

When there are several charged conductors in the field the total flux from one conductor does not in general all end on another single conductor, but, some of the flux lines from No. 1, say, may run to No. 2, some to No. 3, etc. Let ψ_{12} be *that portion* of the flux from any conductor 1 which ends on any other conductor 2, and let V_{12} be the drop of potential from 1 to 2, then the capacity between conductor No. 1 and conductor No. 2 is

$$C_{12} = \frac{\psi_{12}}{4\pi V_{12}}. \tag{21b}$$

Or, calling Q_{12} that portion of the charge on No. 1 which is balanced by an equal and opposite charge on No. 2, the capacity between 1 and 2 is

$$C_{12} = \frac{Q_{12}}{V_{12}}. \tag{21c}$$

Units of Capacity.—The unit of capacity in the practical system of units is the farad (*see Units, Practical Electric*), but as this is a very large unit, a unit equal to one-millionth of a farad, called the microfarad, is usually employed. The c.g.s. electrostatic unit may be called the statfarad and the c.g.s. electromagnetic unit the abfarad. See *Units and Conversion Factors.*

Factors Upon Which Capacity Depends.—The capacity of a given portion of a dielectric depends upon (a) the dielectric coefficient k of the dielectric, (b) the length of the dielectric flux lines through it, (c) the cross-section of the dielectric at right angles to the flux lines, and (d) upon the distribution of the flux lines over this cross-section. Compare with electric conductance. In

general, the capacity of any portion of a dielectric bounded laterally by flux lines and at the ends by equipotential surfaces (Fig. 10) can be expressed by the formula

$$C = \frac{k\psi}{4\pi \int D\,dl}, \tag{21d}$$

where k is the dielectric coefficient, ψ the total dielectric flux through the given portion of dielectric, dl any elementary length along one of the flux lines and D the dielectric flux density at this point, the integral being taken along the flux line from one end surface to the other. When the end surfaces are conductors charged with $+Q$ and $-Q$ units respectively, then

$$C = \frac{KQ}{\int D\,dl}. \tag{21e}$$

By the application of this formula the capacity of various practical forms of condensers may be calculated; see the article on *Capacity and Charging Current, Calculation of.* It should be noted that the capacity of a condenser depends upon the *distribution* of the dielectric flux (k being assumed constant), but not upon the absolute value of the flux; i.e., for a given dielectric and given distribution of flux the capacity is a constant. In general, when any conductor or dielectric of a different specific inductive capacity is placed in the electric field set up by the charged plates of a condenser, the distribution of the flux, and therefore the capacity of the condenser, is altered.

Relation Between Conductance and Capacity. — Comparing equations (9a) and (21d), it is apparent that when the dielectric flux lines and the current stream lines have the same distribution in any given region, the ratio of the conductance of this region is $4\pi\gamma/k$ where k is the dielectric coefficient and γ the conductivity of the material in this region. Hence the formulas for the capacity and conductance of the dielectric between the plates of any shape or size of condenser differ only by a constant coefficient. That is, if C is the capacity of any condenser, then

$$g = \frac{4\pi\gamma}{k} \cdot C \tag{22}$$

is the conductance of the dielectric between its plates. Values of C for various cases are given in the article on *Capacity and Charging Current.*

Charge and Discharge of a Condenser. — To charge a condenser a difference of electric potential must be established between its plates. This may be done, as noted above, by connecting the two plates of the condenser respectively to the two terminals of any source of e.m.f., see Fig. 11. If the dielectric has a very high resistance and the source of e.m.f. has a constant value E, the current set up in this circuit will continue only until a difference of potential equal to E has been established across the two plates of the condenser, or until a charge equal to CE has been transferred from the "negative" to the "positive" plate of the condenser. The establishment of the electric flux through the dielectric of the condenser may be looked upon as setting up in the dielectric itself an opposing force analogous to the opposing force set up in a spring when it is compressed. When the opposing force just balances the impressed force a steady state is attained, just as the compressing of a spring ceases

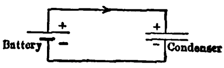


Fig. 11.

when the force producing the compression is just balanced by the opposing force due to the elasticity of the spring.

When a condenser has thus been charged, the wires connecting it to the source of e.m.f. may be removed and the condenser remains charged for a length of time depending upon the resistance of the dielectric separating the plates; the higher this resistance the longer the time that the condenser remains charged. The plates may also be moved apart and they still retain their charges, one plate a positive charge and the other a negative charge, but the distribution of these charges on the plates will in general become altered. Experience shows that a mechanical force is required to separate the charged plates irrespective of whether or not they are connected to the source of e.m.f.

When the two charged plates are "short-circuited" by a wire, as shown in Fig. 12, a momentary current is established through the wire and the electric field between the plates and the charges disappear. The quantity of electricity discharged through the wires is equal to the quantity of charge originally on either plate. A charged condenser, therefore, acts like a source of e.m.f., the direction of this e.m.f. *around* the circuit containing the condenser being in the direction *through* the condenser from its negative to its positive plate. A condenser when it is being charged may also be looked upon as producing a back e.m.f., that is, an e.m.f. opposing the e.m.f. which charges it. When a condenser is considered from this point of view only the *conducting* portion of the circuit is to be considered in applying Kirchhoff's Laws. When the condenser has an appreciable leakage its resistance must be considered to be in *parallel* with its e.m.f.

Fig. 12.

Charging or Capacity Current and Leakage Current. — The displacement current through the dielectric of a condenser is frequently called the "charging" or "capacity" current. The conduction current through the dielectric is called the "leakage" current. Let C be the capacity of the condenser, g the conductance of the dielectric, and v the voltage across the condenser, then the total current through the condenser is

$$i = gv + C\frac{dv}{dt}, \tag{23}$$

where $\frac{dv}{dt}$ represents the rate of change of v with time. The component gv of this current is the leakage current and the component $C\frac{dv}{dt}$ is the charging or capacity current.

Capacities in Series. — When several capacities* are connected end to end so that the *same dielectric flux* passes through each of them, they are said to be "in series." The total capacity of any number of individual capacities C_1, C_2, C_3, etc., connected in series is C where

$$\frac{1}{C} = \frac{1}{C_1} + \frac{1}{C_2} + \frac{1}{C_3} + \ \dots \tag{24}$$

Compare with conductances in series, equation (11b).

Capacities in Parallel. — When several capacities* are connected between the same pair of equipotential surfaces so that the *same potential drop* is established through each, they are said to be "in parallel." *When there are no e.m.f.'s*

* Either condensers, or dielectrics of different kinds, sizes or shapes in contact along ...tential surfaces.

in any of the circuits between the two equipotential surfaces the total equivalent capacity of any number of capacities C_1, C_2, C_3, etc., connected in parallel is

$$C = C_1 + C_2 + C_3 \ldots \tag{25}$$

Compare with conductances in parallel, equation (12a).

SPECIFIC INDUCTIVE CAPACITY (K) AND DIELECTRIC COEFFICIENT (k). — From equation (21d) it is evident that when the capacity of a given condenser is measured (1) when a dielectric A is between the plates and (2) when some other dielectric B is between these plates, then the ratio of the two capacities is the same as the ratio of the dielectric coefficients of the two dielectrics. The "specific inductive" capacity of any dielectric is defined as the ratio of the capacity of a condenser having this substance as its dielectric to the capacity of the same condenser when air forms the dielectric between the plates. The specific inductive capacity is, therefore, independent of the system of units employed.

The c.g.s. electrostatic system of units is based on the arbitrary choice of unity as the dielectric coefficient of air; hence, in the c.g.s. electrostatic system of units the specific inductive capacity and the dielectric coefficient are numerically equal. In the c.g.s. electromagnetic system of units the dielectric coefficient of air is not unity but $\frac{1}{9 \times 10^{20}}$ (i.e., the reciprocal of the square of the velocity of light in air). In the practical system of units, when the centimeter is taken as the unit of length, the dielectric coefficient of air is $\frac{1}{9 \times 10^{11}}$. Hence, calling K the specific inductive capacity of any dielectric referred to air as unity, and k its dielectric coefficient, then in the

c.g.s. electrostatic system $\quad k = K,$

c.g.s. electromagnetic system $\quad k = \frac{K}{9 \times 10^{20}},$

Practical system (cm. as unit of length) $\quad k = \frac{K}{9 \times 10^{11}}.$

Values of the specific inductive capacity of various insulating materials are given in the article on *Insulating Materials, Properties of.*

Electric Absorption and Residual Charge. — The value of the dielectric coefficient k of a given dielectric is not strictly a constant unless the dielectric is perfectly homogeneous. In the case of such nonhomogeneous substances as glass, mica, rubber, paper, cloth, etc., the dielectric coefficient is found to depend upon the time of electrification, i.e., upon the length of time that the voltage is applied, its value increasing with the time of electrification (*see Insulating Materials, Testing of*). This phenomenon is sometimes described as "electric absorption," the idea being that the charge from the plates of the condenser soaks into the dielectric, for an increase in the dielectric coefficient for a given impressed voltage means a greater quantity of electricity conducted to the plates. This idea is also in accord with the experimental fact that when such a condenser is discharged by short-circuiting it with a wire, Fig. 12, the wire then being removed, a "residual" charge appears on the plates after a lapse of a few seconds.

Dielectric Hysteresis. — A phenomenon closely associated with electric absorption is the fact that when the electric field in a heterogeneous dielectric is caused to vary rapidly an amount of heat is dissipated in the dielectric greatly in excess of that which can be accounted for in terms of its leakage resistance as determined by continuous-current measurements. This may be due in part to

an actual increase in the resistance of the dielectric with the speed of variation of the field, or may be due to a phenomenon analogous to magnetic hysteresis, i.e., to a lag of the dielectric flux density behind the electric field intensity (*see Magnetic Materials, Properties of*). Whatever may be the cause of this extra loss of power for rapidly varying fields, it is generally described as the loss due to "dielectric hysteresis." The heat developed is in many cases quite appreciable. See also the article on *Condensers, Electric.*

DIELECTRIC STRENGTH. — ELECTRIC SPARK AND ELECTRIC CORONA. — Experience shows that when an electric field is established in a dielectric and the intensity of this field is increased, a point is reached at which the dielectric loses its insulating property and becomes a conductor. This condition of affairs is usually accompanied by a spark which burns a hole through the dielectric, i.e., the dielectric is "punctured." Under other conditions the breakdown may not be permanent, but may result in the acquisition of a high conductivity by the dielectric only while the voltage gradient is maintained above the critical value, the dielectric regaining its insulating property when the field is reduced below this critical value. This latter condition is usually described as the formation of an electric "corona" in the dielectric; in the case of air the formation of corona manifests itself by a bluish light in the air around the conductors between which the field is established. Whether the breakdown produced by a given voltage is of the nature of a puncture or results in the formation of a corona depends chiefly upon the *distribution* of the dielectric flux produced in the dielectric (*see Corona, Electric*).

The critical field intensity or voltage gradient at which breakdown occurs is called the "dielectric strength" of the dielectric. The dielectric strength depends upon the nature of the dielectric, its value for the various dielectrics ordinarily employed in practice depending decidedly upon their chemical and physical nature (*see Insulating Materials, Properties of*). It is also found that for a given dielectric the critical voltage *gradient* at which breakdown occurs depends in general upon (*a*) the distribution of the dielectric flux just prior to breakdown and (*b*) upon the thickness of the dielectric. It is naturally to be expected that the *voltage* (total potential difference) required to produce a breakdown would depend upon the distribution of the dielectric flux and the thickness of the dielectric, for the voltage gradient at all voltages depends upon these factors (*see above under Capacity*), but there is as yet no satisfactory explanation of the dependence of the *critical gradient* upon these factors.

In fact, but little is known regarding the nature of an electric breakdown, and even the values of the dielectric strength are known only approximately in most instances, for in many of the tests made to determine its value the distribution of the electric flux was not known. The values of the dielectric strength given in the article on *Insulating Materials, Properties of*, must, therefore, be considered only as rough approximations except for conditions identical with those under which the tests were made.

ELECTROSTATIC ENERGY. — From the general relations expressed by equations (15) and (23) it is evident that when the potential difference between the plates of a condenser is increased from 0 to V the energy input is

$$\int_0^t gv^2\,dt + \int_0^V Cv\,dv.$$

The energy represented by the first term on the right-hand side of this equation is dissipated as heat in the dielectric, but the energy represented by the second term, which, when C is constant, may be written

$$W = \tfrac{1}{2}CV^2, \qquad (26)$$

does not represent a dissipation of heat; this is a fact of experience. Moreover, when the condenser is discharged, by short-circuiting its plates with a wire, this same amount of energy ½ CV^2 is transferred to the wire. Hence, the energy represented by ½ CV^2 is said to be stored in the condenser, or preferably in the *dielectric* of the condenser, for the electric force F exists only in the dielectric. This stored energy is called the "electrostatic" energy. It is analogous to the energy stored in a spring when the latter is compressed or stretched. Equation (26) may also be written

$$W = \frac{1}{2}\frac{Q^2}{C} = \frac{1}{2}QV = \frac{1}{8\pi}\psi V\cdot \tag{26a}$$

The electrostatic energy *per unit volume* of an electric field may be written

$$w = \frac{DF}{8\pi} = \frac{kF^2}{8\pi} = \frac{D^2}{8\pi k}, \tag{26b}$$

where k is the dielectric coefficient, F the electric field intensity or potential drop per unit distance, and D the dielectric flux density or flux per unit area perpendicular to the direction of the drop.

It should be noted that equations (26) to (26b) are based on the assumption that k is a constant, independent of the value of F. When this condition does not hold, the energy required to establish the field is $\int_0^V Cv\,dv$, the evaluation of which depends upon the relation between C and v.

MECHANICAL FORCES IN AN ELECTROSTATIC FIELD.— Experience shows that all bodies (conductors or insulators) in an electric field exert in general mutual mechanical forces upon one another tending to produce such a relative motion as will *decrease* the energy of the field. Let f be the component of the force tending to move any body in the field in a given direction and let dW be the *increase* in the energy of the field due to displacing the body a distance dx in this direction, then

$$f = -\frac{dW}{dx}, \tag{27}$$

provided this displacement does not cause a change in the existing electric charges in the field. As a consequence of this general relation it can be shown that every charged surface exerts a force of repulsion on every other surface charged with electricity of the same sign, and a force of attraction on every surface charged with electricity of the opposite sign.

In the special case of the two conductors forming a condenser the force of attraction exerted by one conductor on the other is

$$f = -\frac{V^2}{2}\frac{dC}{dx}, \tag{27a}$$

where V is the p.d. across the condenser, C the capacity of the condenser, and dC represents the increase in the capacity of the condenser when one conductor moves a distance dx away from the other. This relation results from the substitution of (26a) in (27). For example, the capacity of a parallel plate condenser is approximately,

$$C = \frac{kA}{4\pi x},$$

where k is the dielectric coefficient, A the area of the smaller plate, and x the distance between the plates. Hence the force of *attraction* is

$$f = \frac{V^2kA}{8\pi x^2}.$$

Principle of the Electrometer. — This relation suggests a method of measuring potential difference, for, by transposing,

$$V = x\sqrt{\frac{8\pi f}{kA}}.$$

If the force acting on the upper plate is measured by means of a balance, and if A and x are also measured, and the dielectric between them is air ($k = 1$ in the electrostatic system, by definition), then all the data necessary for the calculation of V is at hand. The above formula for V is approximate only, since the capacity formula is approximate, due to the assumption of a uniform flux density in the dielectric between the plates. As a matter of fact the flux density near the edges of the plate is not uniform, but it is possible to correct for this non-uniformity; see article on *Electrometers*.

MAGNETS AND MAGNETIC SUBSTANCES. — A magnet may be defined as any body which possesses the property of attracting pieces of iron or steel* and which when freely suspended takes up a definite position with respect to the geographical meridian. A magnetic substance is any body which acquires this property when it is placed near a magnet or near a conductor carrying an electric current. A body which is given this property is said to be "magnetized." A magnetic needle is a magnetized needle of iron or steel; the north seeking end of such a needle is called its north pole and the south seeking end its south pole. When such a needle is freely† suspended near a magnet or a conductor carrying an electric current a couple is bound to be exerted upon it which causes it to take up a definite direction. The needle is said to "point" in the direction of a line drawn through it from its south to its north pole.

MAGNETIC FIELD OF FORCE. — Any region in which a magnetic substance (e.g., a piece of soft iron), when placed therein, becomes magnetized is said to be a "magnetic field." A magnetic field exists in and around every magnetized substance and around every stream line of electric current. The direction of the magnetic field at any point P is arbitrarily chosen as the direction in which a small magnetic needle point would point when placed at P without disturbing appreciably the existing conditions.

Magnetic Flux (ϕ). — Consider a small closed turn of wire, Fig. 13, placed in a magnetic field with its plane perpendicular to the direction of the field. Experience shows that when such a turn of wire is removed from the field in any manner whatever (the coil remaining short-circuited on itself or forming part of a closed circuit), or when the magnetic field is caused to disappear in any manner whatever, a momentary electromotive force is set up or "induced" in this coil, which in turn causes a momentary electric current to flow through the coil. This e.m.f. exists only while the coil is *moving across* the field or while the field through the coil is *varying*.

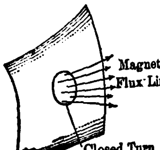

Fig. 13.

* With a force in excess of the gravitational force, which latter is extremely small.

† A needle is said to be freely suspended when there is no controlling force exerted upon it through its suspension tending to make it take up any definite position.

The time integral of the induced e.m.f. when the coil is removed entirely from the magnetic field is taken as the measure of the "magnetic flux" existing through the coil when in its original position. That is, calling e the e.m.f. induced in the coil at any instant due to its motion through the field, and t the time during which the e.m.f. exists in the coil, then the magnetic flux through the coil when in its original position is

$$\phi = \int_0^t e\, dt. \tag{28}$$

This quantity is readily measured by means of a ballistic galvanometer; see *Magnetic Testing*.

Units of Magnetic Flux.—The unit of magnetic flux in the c.g.s. electromagnetic system is frequently called a "maxwell" or simply a "line." The unit of flux in the practical system of units is sometimes called a "weber"; see *Units and Conversion Factors*.

Magnetic Flux Density (B).—Experience shows that the magnetic flux through any closed loop, such as the turn of wire described above, depends upon the area inclosed by this loop. The magnetic flux per unit area through any surface perpendicular to the direction of the field is defined as the "magnetic flux density" at this surface, and is usually represented by the symbol B. By the flux density at any *point* is meant the flux density at an infinitely small surface drawn perpendicular to the field at this point. The direction of the magnetic flux density at any point is the same as that in which a magnetic needle would point if placed at this point; i.e., the direction of the flux density and the direction of the magnetic field are the same. When the flux density has the same value B at every point of a surface of area A and is perpendicular to this surface, then the total flux through this surface is

$$\phi = BA. \tag{29}$$

The total magnetic flux across any surface S may in general be expressed mathematically by the surface integral

$$\phi = \int (B \cos \alpha)\, ds, \tag{29a}$$

where ds represents any elementary area of this surface and $(B \cos \alpha)$ the component of the flux density perpendicular to ds.

Units of Magnetic Flux Density.—The unit of magnetic flux density in the c.g.s. electromagnetic system is called the "gauss"; no name has been given to the corresponding practical unit.

Magnetic Flux Lines. — Continuity of Magnetic Flux.—Magnetic flux can be represented by lines drawn in the field in such a direction that their direction coincides at each point with the direction of the field at that point, and of such a number that their density at each point (number per unit area perpendicular to their direction) is equal to the magnetic flux density at that point. Such lines are called "magnetic flux lines." Experience shows that lines thus drawn in a magnetic field always form *closed* loops, i.e., a magnetic flux line has no ends. As a consequence of this fact the total magnetic flux coming up to any surface in a magnetic field is always equal to the total flux leaving that surface. (Compare with stream lines of electric current.) When the flux

NOTE.—ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

leaving a surface is considered as equivalent to a negative flux coming up to that surface, this relation may be expressed by the formula

$$\Sigma\phi = 0 \tag{30}$$

at every surface, the summation being an algebraic one. This is analogous to Kirchhoff's first law for electric circuits.

Magnetic Fields Due to Electric Currents. — Experience shows that every stream line of electric current is always accompanied by a magnetic field the flux lines of which *link* the stream line of current. That is, the flux lines thread the loops formed by the stream lines and the stream lines thread the loops formed by the flux lines; see Fig. 14.

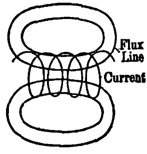

Fig. 14.

Right-handed Screw Law. — The direction of the current flowing around any electric circuit and the direction in which the flux lines due to that current thread this circuit are related to each other in the same manner as the direction of motion of a point on the edge of the head of a right-handed screw placed at the center of the circuit and the direction of advance of the screw. Or, if one faces the electric circuit looking in the direction of the flux lines threading it, the current producing these lines is in the clockwise direction around the circuit. The relative direction of the current and its magnetic flux may be briefly described by saying that the current is in the right-handed screw direction with respect to the flux which it produces.

MAGNETICALLY INDUCED ELECTROMOTIVE FORCE. — The measure of magnetic flux is based on the experimental fact that whenever the magnetic field threading an electric circuit changes, an electromotive force is induced in that circuit. When the circuit is formed by a single turn of wire this induced e.m.f. is, from the definition above, equal to the rate of change of this flux with respect to time, i.e., $e = \frac{d\phi}{dt}$. When the circuit is in the form of a coil each turn of which links the flux, the e.m.f. induced in *each* turn is equal to $\frac{d\phi}{dt}$ where ϕ is the flux which links that particular turn. When each turn links the *same number of flux lines*, then the total induced e.m.f. in a coil of N turns is

$$e = N\frac{d\phi}{dt}. \tag{31}$$

When the change in flux is due to a motion of a circuit or part of a circuit through a magnetic field the induced e.m.f. in any conductor is also equal to the number of flux lines which *cut across* this conductor.

Magnetic Linkages (λ). — The condition that each turn be linked by the same flux ϕ is seldom the case; some of the flux lines link only part of the turns, see Fig. 14. In general, the total e.m.f. is

$$e = \frac{d}{dt}(\phi_1 + \phi_2 + \ldots \phi_n),$$

where ϕ_1, ϕ_2, etc., represent the fluxes linking the various turns. The sum $(\phi_1 + \phi_2 + \ldots \phi_n)$ may be called the total number of "magnetic linkages" and may be conveniently represented by the symbol λ, viz.,

$$\lambda = \phi_1 + \phi_2 + \ldots \phi_n,$$

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

and the total induced e.m.f. may then be written

$$e = \frac{d\lambda}{dt}. \qquad (31a)$$

When all the N turns link the same flux, ϕ, then $\lambda = N\phi$.

Direction of the Induced E.M.F. — The direction of this induced e.m.f. around the circuit is found to be in the *left-handed* screw direction with respect to the *increase* of flux; viz., if one faces the circuit looking in the direction of the *increase* of flux, the induced e.m.f. is in the counter-clockwise direction. The current which would be set up by this e.m.f., however, would produce a flux linking the circuit in the right-handed screw direction. Hence a change in the magnetic flux through an electric circuit always sets up an e.m.f. which tends to produce a current around this circuit in such a direction as to set up an *opposing* flux. This fact may be expressed mathematically by writing a minus sign before $\frac{d\phi}{dt}$ in equation (31), i.e., by putting

$$e = -N\frac{d\phi}{dt}. \qquad (31b)$$

The value of $\left(-N\frac{d\phi}{dt}\right)$ is then the e.m.f. induced in the circuit in the right-handed-screw direction with respect to the increase of flux. Or stated in other words $\left(-N\frac{d\phi}{dt}\right)$ represents the *rise* of electric potential and $N\frac{d\phi}{dt}$ represents the *drop* of potential around the circuit in the right-handed screw direction with respect to the increase of flux.

WORK DONE BY A VARYING MAGNETIC FLUX. — Consider a coil A (Fig. 15) of N turns of wire, and let each of these N turns be linked by a flux ϕ due to some external agent, e.g., another coil B in which an electric current is flowing. Let the flux ϕ through A due to B be increasing at any instant at the rate $\frac{d\phi}{dt}$ in the *left-handed* screw direction with respect to the current I in A at this instant. Then there is induced in A at this instant an e.m.f. in the direction of I equal to $E = N\frac{d\phi}{dt}$ and, therefore, the electric

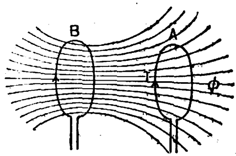

Fig. 15.

power developed in A at this instant is $ei = NI\frac{d\phi}{dt}$. This power is transmitted to the coil A as a result of the varying flux through it; hence the power

$$p = NI\frac{d\phi}{dt} \qquad (32)$$

may be looked upon as the magnetic power input, this power being converted within the coil into electric power.

Magnetic Displacement Current. — The varying flux established by B through A may be looked upon as the means whereby this energy is transferred through the magnetic field, just as an electric current may be looked upon as the means whereby energy is transferred from one point to another in an

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

electric circuit. Hence the varying flux may be looked upon as a "magnetic displacement current."

Magnetomotive Force ($\mathfrak{F}$). — The above expression for the rate of transfer of energy by a varying magnetic field may be compared with the rate of transfer of energy, or power input $P = EI$, corresponding to an electric current I flowing in a circuit in which there is *back* electromotive force E. The strength of the "magnetic displacement current" may be chosen arbitrarily* as

$$\text{Magnetic displacement current} = \frac{1}{4\pi}\frac{d\phi}{dt},$$

just as the strength of the electric displacement current is taken as $\frac{1}{4\pi}\frac{d\psi}{dt}$, where ψ is the electrostatic flux density. Then the quantity corresponding to the electromotive force must be chosen numerically equal to

$$\mathfrak{F} = 4\pi NI \qquad (33)$$

and may be called the "magnetomotive force," abbreviated "m.m.f." The magnetic power input may then be written

$$p = \mathfrak{F} \times (\text{Magnetic displacement current}).$$

where $\mathfrak{F}$ is the *back* magnetomotive force.

Direction of the Magnetomotive Force. — The closed path of the magnetic flux lines through a magnetic field is called a "magnetic circuit," just as the path of the stream lines of an electric current is called an electric circuit. In general, a magnetomotive force is produced in every magnetic circuit wherever it is linked by an electric circuit, equal in numerical value to $4\pi NI$, where N is the number of times the current I links this circuit. The magnetomotive force is taken as positive when the current links the flux lines in the right-handed screw direction, for then an increase in the flux corresponds to a magnetic power output. When the current links the flux lines in the left-handed-screw direction the magnetomotive force is taken as negative, i.e., a "back" magnetomotive force, for in this case an increase in flux corresponds to a magnetic power input; see the special case considered above.

Units of Magnetomotive Force. — Ampere-Turns. — The product NI in the expression for the magnetomotive force, equation (33), is called the "current-turns"; when I is expressed in amperes it is called the "ampere-turns." The magnetomotive force as above defined differs from this product only by a constant numerical factor; hence the ampere-turns of a coil may be taken as a measure of the magnetomotive force produced by it. This unit of magnetomotive force, namely, one ampere-turn, is the unit commonly employed in the practical calculation of magnetic circuits. The c.g.s. electromagnetic unit is called the gilbert; 1 ampere-turn = 1.2566 gilberts. See *Units and Conversion Factors*.

MAGNETIZING FORCE OR MAGNETIC FIELD INTENSITY (H). — Experience shows that the magnetic flux density produced at any point by a given magnetomotive force depends (*a*) upon the position of the point with respect to the source of the m.m.f. and (*b*) upon the nature of the substances through which this m.m.f. produces the magnetic flux. Compare with the electric current density or dielectric flux density produced at a given point by

* The factor 4π arises from the manner in which the conceptions of the magnetic field were originally developed.

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

a given electromotive force. These facts lead to the conception of the flux density at any point in a magnetic field as being due to a "magnetizing force" H at that point, this magnetizing force H depending solely upon the *magnetomotive forces* producing the field and the *distribution of the flux lines*, as distinguished from the flux density B which depends not only upon these two items but also upon the *nature of the medium at the point in question*.

From analogy with the relation between electromotive force and electric field intensity, the magnetizing force (also called the "magnetic field intensity") at successive points along any closed path in a *magnetic* field may be defined by the relation that its line integral around such a path is equal to the total magnetomotive force acting around this path, viz.,

$$4\pi NI = \int (H \cos \theta) dl, \tag{34}$$

where dl represents any elementary length of this path, see Fig. 16, $(H \cos \theta)$ the value of the component of the magnetizing force at dl in the direction of dl, and NI the total number of current turns linked by the path. Experience shows that such a definition leads to a simple means of expressing in a quantitative manner the interrelations of a number of experimental facts. Magnetizing force may also be expressed as the force in dynes which would act on a "unit magnetic pole," see p. 412.

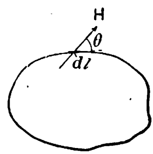

Fig. 16.

When the path coincides in direction with the magnetizing force at each point, equation (34) may be written

$$4\pi NI = \int H dl. \tag{34a}$$

For the application of this formula see the articles on *Magnetic Properties of Iron; Generators; Motors.*

Direction of the Magnetizing Force. — Experience shows that except for points inside a permanent magnet the magnetizing force H and the flux density B are always in the same direction. For points inside a permanent magnet the direction of the magnetic field intensity H, due solely to the magnet itself, is opposite to the direction of the flux lines, i.e., a permanent magnet produces a "demagnetizing force" on itself.

Lines of Magnetizing Force. — The magnetizing force at any point in a magnetic field may be represented by lines drawn in the field in such a direction that their direction coincides with the direction of the magnetizing force at each point, and of such a number per unit area perpendicular to their direction that their density at each point gives the value of the magnetizing force at that point. Such lines are called "lines of magnetizing force" or "lines of magnetic field intensity." In general the lines of magnetizing force and the magnetic flux lines coincide in direction (except within the substance of permanent magnets), *but their densities are different*. Only in non-magnetic substances do the flux lines and lines of magnetizing force coincide. The simple expression "lines of force" is frequently used to designate either the flux lines or the lines of magnetic intensity, but it is evident that such a loose use of this term is liable to lead to confusion when speaking of the magnetic field within a magnetic substance.

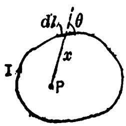
Units of Magnetizing Force. — Magnetizing force is of the nature of magnetomotive force per unit length, just as electric field intensity is of the nature

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

of electric potential difference per unit length. Hence the c.g.s. electromagnetic unit of magnetizing force may be called the "gilbert per centimeter"; compare with volts per centimeter. When the magnetomotive force is expressed in ampere-turns, the magnetizing force is expressed in ampere-turns per centimeter or per inch; see *Units and Conversion Factors.*

Values of the Magnetizing Force in a Uniform Medium. — When the medium surrounding the stream lines of an electric current is of a *uniform magnetic nature throughout,* the magnetizing force at any point may be calculated from the shape and distribution of the stream lines of the current, irrespective of whether the medium be non-magnetic or highly magnetic, e.g., iron. See *Units and Conversion Factors* for numerical multipliers to change them into practical units.

Magnetizing Force at any Point Due to an Element of a Current-Stream Line (Fig. 17). — Consider any closed stream line of electric current and let the surrounding *medium be uniform* in its magnetic properties throughout the region in which the magnetic field produced by this stream line exists. It can be shown that each elementary length dl of this stream line may be considered as contributing to the magnetizing force H at any point P in this region an amount

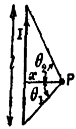


$$dH = \frac{(I \sin\theta)\, dl}{x^2}, \qquad (35)$$

Fig. 17.

where I is the current flowing along this stream line, x the distance from P to dx, and θ the angle between x and dl. The direction of dH is perpendicular to the plane determined by x and dl. The total magnetizing force at P is then the *vector sum* or *vector integral* of dH for all the elementary lengths into which the stream line is divided.

Magnetizing Force Due to a Straight Wire (Fig. 18). — Applying equation (35) to the case of a straight wire of circular cross-section carrying a current I, the magnetizing force at any point P due to a length l of this wire is



$$H = \frac{I}{x}(\sin\theta_1 + \sin\theta_2), \qquad (35a)$$

where x is the perpendicular distance from P to the wire and θ_1 and θ_2 the angles designated in Fig. 18.

Fig. 18.

When the wire is very long compared with x, this becomes

$$H = \frac{2I}{x}. \qquad (35b)$$

This formula also holds approximately for any point outside a wire of any shaped cross-section, provided x is large compared with the maximum diameter of this section. For a point *inside a long wire of circular cross-section* of radius a the magnetizing force is also given by (35b) when I is taken to represent *that part of the current inside the circle through P* concentric with the axis of the wire. When the current density is uniform over the cross-section, as is usually the case (*see, however, the article on Skin Effect*), the magnetizing force inside the wire is

$$H_i = \frac{2xI}{a^2}. \qquad (35c)$$

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

Magnetizing Force on the Axis of a Circular Coil of N Turns.— Let I be the current, r the mean radius of the coil, and x the distance of the point from the center of the circle; then

$$H = \frac{2\pi NIr^2}{(r^2 + x^2)^{3/2}} \tag{35d}$$

Magnetizing Force due to a Solenoid.— A solenoid is a helical coil of wire, each turn having the same radius. Let N = total number of turns, I = current in abamperes, r = mean radius of the helix in centimeters, l = length of helix in centimeters. Then at any point on the axis of the helix (inside or outside) at a distance of x centimeters from its center, the magnetizing force in gilberts per centimeter is

$$H = \frac{2\pi NI}{l}\left[\frac{0.5\,l + x}{\sqrt{r^2 + (0.5\,l + x)^2}} + \frac{0.5\,l - x}{\sqrt{r^2 + (0.5\,l - x)^2}}\right] \tag{35e}$$

This formula holds only when the thickness of the winding is small compared with the mean radius r. When l is large compared with r this reduces to

$$H = \frac{4\pi NI}{l}, \tag{35f}$$

For all points inside the solenoid (whether on the axis or not) at a distance from the ends large compared with r, that is, inside the central portion of a long solenoid, the field is uniform over the cross-section of the solenoid and its value is given by (35f).

Magnetizing Force Inside a Toroid (Fig. 19).— A toroid is a cylinder bent into the form of a closed ring, making a shape like a doughnut. When such a ring is *uniformly* wound with an insulated wire so that the turns of the wire are close together and cover the entire surface of the toroid, the magnetic field is confined entirely within the space inclosed by these turns, and therefore, when the core on which the wire is wound is of uniform magnetic material throughout, both the lines of magnetizing force and the flux lines must be circles concentric with the hole in the "doughnut." The magnetizing force will have the *same* value at every point on the circumference of any *one* of these circles, and, therefore, from equation (34a) the value of H at any point P within the core is

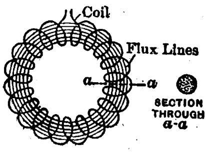


Fig. 19.

$$H = \frac{4\pi NI}{l}, \tag{35g}$$

where N is the total number of turns on the core, I the current in each turn and l the length of the circumference through P. Unless the hole in the "doughnut" has a large radius compared with the radius of the cross-section of the core H will not be uniform over this section, since l for the various points in the cross-section will differ considerably.

It should be noted that the value of H is independent of the material of the core provided only that the core be of uniform material throughout. That is,

NOTE.—ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS

equation (35g) applies to an iron core as well as to an air or wood core, provided the iron is uniform throughout and there is no air gap across the path of the flux lines. Even a mechanically perfect contact between two pieces of iron of the same kind, however, is sufficient to vitiate the above formula.

MAGNETIC PERMEABILITY (μ). — PARAMAGNETIC AND DIAMAGNETIC SUBSTANCES. — The quotient of the magnetic flux density B at any point by the magnetizing force H at that point is defined as the "magnetic permeability" μ of the substance as medium at that point, viz.,

$$\mu = \frac{B}{H}. \tag{36}$$

Compare with the definition of dielectric coefficient, equation (17.) The c.g.s. electromagnetic system of units is based on the arbitrary assumption of unity as the value of the magnetic permeability of air. Any substance which has a magnetic permeability greater than that of air is called a "paramagnetic substance," and any substance which has a permeability less than that of air is called a "diamagnetic substance." The only substances which are strongly paramagnetic, i.e., which have a permeability considerably greater than that of air, are iron, steel, nickel and cobalt, and certain alloys of non-magnetic elements. The only substance which is appreciably diamagnetic is bismuth, which has a permeability of about 0.9998. All other elements are practically non-magnetic, i.e., their permeabilities differ from unity by less than 1 per cent.

The permeability of a given sample of any highly magnetic substance is not a constant, but depends upon the value of the magnetizing force; see the curves in the article on *Magnetic Properties of Iron*. The permeability also depends very largely upon the previous heat treatment and the exact composition of the material, and also upon its previous magnetic history; these relations are also discussed in detail in that article. The methods of measuring permeability are described in the article on *Magnetic Testing*.

North and South Poles. — That portion of the surface of any magnetized body from which the flux lines pass out into the air (or into any substance of lower permeability) is said to be a north magnetic pole, and that portion of the surface at which the flux lines enter the body is said to be a south magnetic pole. A "unit north pole" is a pole from which 4π flux lines emerge into the surrounding air. When a magnetic needle is placed near the surface of a magnetized body its north seeking end points away from this surface when this surface is a north pole and toward the surface when this surface is a south pole.

Difference of Magnetic Potential (U). — Consider any two points 1 and 2 in a magnetic field (Fig. 20) and let the path between them from 1 to 2 pass through an electric circuit producing a magnetomotive force in the direction from 1 to 2, then from analogy with the electric circuit, equation (2), the expression

$$U_{12} = \int_1^2 (H\cos\theta)\, dl - \mathfrak{F}_{12} \tag{37}$$

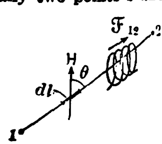

Fig. 20.

is called the "drop of magnetic potential" from 1 to 2. From the definition of magnetizing force, equation (34), it follows that around any *closed* circuit the drop of magnetic potential is always zero. A magnetomotive force $\mathfrak{F}_{12}$ is, therefore, equivalent to a rise of magnetic potential from 1 to 2.

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

When there is no source of m.m.f. between 1 and 2 and the path coincides with a line of magnetizing force, the drop of magnetic potential is

$$U_{12} = \int_1^2 H\, dl. \tag{37a}$$

Magnetic potential difference is of the same nature as magnetomotive force and may, therefore, be expressed in the same units, viz., gilberts or ampere turns.

Magnetic Equipotential Surfaces. — A surface drawn in a magnetic field in such a manner that this surface is perpendicular at each point to the magnetizing force at this point (i.e., to the line of magnetizing force through this point) is called a "magnetic equipotential surface," compare with *electric equipotential surface.*

Magnetic Reluctance ($\mathcal{R}$). — To establish a magnetic flux ϕ through a given portion of a substance which is *not itself linked by a source of m.m.f.*, a difference of magnetic potential must always be established between the end surfaces of this substance. Let U be the magnetic potential drop established from one surface to the other, then the quotient

$$\mathcal{R} = \frac{U}{\phi} \tag{38}$$

is defined as the magnetic reluctance of the given portion of the substance. Compare with electric resistance. The c.g.s. electromagnetic unit of reluctance is called the oersted. It should be noted that the above definition is meaningless except when applied to a portion of a substance of which the end surfaces are magnetic equipotential surfaces and through every cross-section of which the same flux passes.

Factors Upon Which Reluctance Depends. — The magnetic reluctance of a given portion of a substance included between two equipotential surfaces and bounded laterally by a surface through which no flux line passes depends upon 1. the magnetic permeability of the substance, 2. the dimensions of this portion of the substance and 3. upon the distribution of the flux lines over each cross-section perpendicular to them. The relations are identical with those which determine the electric al resistance of a conductor, the magnetic permeability taking the place of the electric conductivity. For example, for a straight bar of constant cross-section A and length l, through which the flux lines are straight, parallel and uniformly distributed, the reluctance is

$$\mathcal{R} = \frac{l}{\mu A}. \tag{38a}$$

Magnetic reluctance is not a constant quantity even for a given material and given flux distribution, unless this material is non-magnetic. For all highly magnetic materials μ depends upon the magnetizing force and therefore also upon the flux density. It should also be noted that the magnetic reluctance does not represent a "resistance" in the sense of something which causes a dissipation of energy.

Magnetic Permeance ($\mathcal{P}$). — The reciprocal of magnetic reluctance is called "magnetic permeance." The permeance of a straight bar under the conditions specified above is

$$\mathcal{P} = \frac{\mu A}{l} \tag{39}$$

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

The permeability of a substance is, therefore, equal to the permeance of a unit cube of this substance when the flux through the cube is parallel to four edges of the cube and is uniformly distributed over the section at right angles to these four edges.

Magnetic permeance is analogous to electric conductance, except that it is not a factor which affects the *dissipation* of energy in a substance. It does, however, enter into the expression for the energy *stored* in a magnetic field in the same way that the electrostatic capacity of a dielectric is a determining factor in the expression for the energy stored in the electric field.

Kirchhoff's Laws for the Magnetic Circuit. — As already noted, equation (30), the total magnetic flux coming up to any surface in a magnetic field is always zero, provided a flux leaving a surface is considered as a *negative* flux coming up to that surface. This fact may be represented by the formula

$$\Sigma\phi = 0 \tag{40}$$

for every surface in the field. Similarly, from the definition of magnetic potential drop, it follows that the *total* magnetic potential drop around any closed circuit is zero, or that the total magnetomotive force acting around any closed circuit is equal to the sum of the reluctance drops around that circuit, which may be represented by the formula

$$\Sigma\mathfrak{F} = \Sigma\mathfrak{R}\phi. \tag{40a}$$

These two equations are identical in form with those representing Kirchhoff's laws for the electric circuit, equation (13). They are, however, not so easy to use for practical calculations, for the magnetic flux is not confined to approximately geometrical lines like the currents in a network of insulated wires, but in general fills all space surrounding the coils which establish the magnetomotive forces; also, when there is iron or other magnetic material in the circuit, the permeability depends on the flux density and the previous history of the iron. (The distribution of magnetic flux in and around an iron circuit is analogous to the distribution of current in and around an uninsulated mass of copper of the same shape as the iron circuit immersed in a liquid having a conductivity about equal to that of carbon.) Only in the special case of a uniformly wound circular ring or toroid are the lines of induction confined *entirely* to an iron circuit; in general a certain number also exist in the air and in whatever other substances are in the vicinity of the iron circuit.

SELF AND MUTUAL INDUCTION. — When the current in a given electric circuit varies with time the magnetic flux accompanying this current also varies with time, and, since this flux links the current which produces it, an e.m.f. is induced in each turn of the circuit equal to the rate at which the flux through this turn is varying, and in such a direction as to *oppose* the change in the current. That is, an *increasing* electric current is always accompanied by a *back* e.m.f. due to the increase in the magnetic flux which accompanies this increase of current. Or, viewed from another point of view, an increase in the velocity of a stream of electricity develops a back pressure, just as when the velocity of a stream of water is increasing it develops a back pressure or "velocity head" due to the inertia of the water. The magnetic field accompanying an electric current may, therefore, be looked upon as a result of its "electromagnetic inertia," or "electromagnetic mass"; see also the article on *Electron Theory*.

Again, when an electric current *decreases* its accompanying flux decreases and an e.m.f. is set up in the circuit tending to oppose this decrease, i.e., tending

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

to keep the current from decreasing. This is again analogous to the effect of inertia in the case of ordinary matter.

Coefficient of Self-Induction or Inductance (L). — In general, the coefficient L by which the rate of change of the current $\left(\frac{di}{dt}\right)$ in any circuit must be multiplied to give the self-induced electromotive force e is called the "coefficient of self-induction" or simply the "inductance" of the electric circuit. In general, then, the self-induced e.m.f. in an electric circuit is

$$e = L\frac{di}{dt}, \qquad (41)$$

where L is the inductance of the electric circuit and $\frac{di}{dt}$ represents the change in the current per unit of time. Since $e = \frac{d\lambda}{dt}$, see equation (31a), where λ is the number of magnetic linkages between the electric circuit and the flux established by the current i, the inductance may also be defined by the relation

$$L = \frac{d\lambda}{di}. \qquad (42)$$

That is, the *inductance is equal to the increase in the number of linkages per unit increase in the current.* When the permeability of the magnetic circuit is *constant* the inductance is also a constant equal to the linkages per unit current. When every flux line is linked by every stream line of electric current, and the permeability of the entire magnetic circuit is constant, then

$$L = \frac{4\pi N^2}{\mathcal{R}}, \qquad (42a)$$

where N is the number of turns forming the electric circuit and $\mathcal{R}$ is the reluctance of the complete magnetic circuit.

Formulas for the inductance of various electric circuits are given in the article on *Inductance and Inductive Reactance.*

Units of Inductance. — The practical unit of inductance is called the henry; for the relation between the henry and the abhenry and millihenry see *Units and Conversion Factors.*

Coefficient of Mutual Induction. — Mutual Inductance (M). — In general, the coefficient M_{ab} by which the rate of change of the current $\left(\frac{di_a}{dt}\right)$ in a circuit A must be multiplied to give the electromotive force e induced by this current in another circuit B, is called the "coefficient of mutual induction" or simply the "mutual inductance" between A and B; see Fig. 15. In general then, the e.m.f. induced in any circuit B by a varying current i_a in any other circuit A, is

$$e_b = M_{ab}\frac{di_a}{dt}, \qquad (43)$$

where M_{ab} is the mutual inductance between A and B.

It can be shown from the principle of the conservation of energy that the mutual inductance of a circuit A with respect to a second circuit B must be equal

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

to the mutual inductance of B with respect to A, that is, $M_{ab} = M_{ba}$. Whence, the e.m.f. induced in A when the current in B increases by an amount di_b is

$$e_a = M_{ab}\frac{di_b}{dt}.$$

Since $e_b = \frac{d\lambda_{ab}}{dt}$, where λ_{ab} is the number of linkages between the circuit B and the flux through B due to the current i_a, the mutual inductance may also be defined by the relation

$$M_{ab} = \frac{d\lambda_{ab}}{di_a}. \tag{44}$$

That is, the *mutual inductance between two circuits A and B is equal to the increase in the number of magnetic linkages of the circuit B per unit increase of the current in A*, and vice versa. When the permeability of the magnetic circuit is *constant*, the mutual inductance is also a constant equal to the linkages of B per unit current in A, and vice versa. When every flux line linking *both* A and B is linked by every current stream line in both A and B, then

$$M_{ab} = \frac{4\pi N_a N_b}{\mathcal{R}_{ab}}, \tag{44a}$$

where N_a and N_b are the number of turns forming the circuits A and B respectively and $\mathcal{R}_{ab}$ is the reluctance of that *part* of the magnetic circuit through which the flux from A to B passes.

The units of mutual inductance are the same as those of self-inductance; see *Units and Conversion Factors*.

Formulas for mutual inductance for a few special cases are given in the article on *Inductance, and Inductive Reactance*.

Instantaneous Potential Drop Through a Coil. — Consider a coil of wire which has a resistance r and an inductance L. Then when this coil contains no other source of e.m.f. than its own self-induced e.m.f., the expression for the instantaneous potential drop through the coil is

$$v = ri + L\frac{di}{dt}, \tag{45}$$

where i is the instantaneous value of the current and $\frac{di}{dt}$ the increase in this current per unit of time. Compare with the equation

$$i = gv + C\frac{dv}{dt},$$

for the instantaneous current through a condenser, where g is the conductance of the dielectric in the condenser, v the potential drop across it, and $\frac{dv}{dt}$ the increase in the potential drop per unit of time.

When there is another coil near the first coil, and the two coils have resistances r_1 and r_2 and self-inductances L_1 and L_2 respectively, and a mutual inductance M, then the potential drops through them are respectively

$$\left.\begin{aligned} v_1 &= r_1 i_1 + L_1\frac{di_1}{dt} + M\frac{di_2}{dt} \\ v_2 &= r_2 i_2 + L_2\frac{di_2}{dt} + M\frac{di_1}{dt} \end{aligned}\right\} \tag{46}$$

where i_1 and i_2 are the currents in the two coils in the *same* direction.

Effective or "Total" Inductance. — In certain cases of symmetry, when the algebraic sum of all the currents in the field is zero, the voltage drop along any *portion* of a circuit may be represented by an expression of the form

$$v = ri + L\frac{di}{dt},$$

although there may be several electric circuits in the vicinity in which electric currents are flowing. An example of this is the case of the wires of a three-phase transmission line arranged so that they form the three edges of an equilateral prism; see *Inductance and Inductive Reactance*. The coefficient L in this case is called the "effective self-inductance" of this particular portion of the circuit; it really takes into account not only the self-induction of the particular part of the circuit under consideration but also the mutual induction of the rest of the circuit or circuits with respect to this particular portion. Similarly, when the voltage drop in any portion of a circuit involves not only the current i_1 in this circuit but also a current i_2 in some part of this circuit or in some other circuit, the coefficient M_{12} in the expression

$$v_1 = r_1 i_1 + L_1\frac{di_1}{dt} + M_{12}\frac{di_2}{dt}$$

is called the effective mutual inductance of the part 2 with respect to 1 although L_1 may also be due in part to circuit 2.

Leakage Inductance. — In discussing the action of a transformer (q.v.), which is merely two electric circuits linking the same iron core, it is more convenient to deal with the *resultant* flux due to the currents in *both* electric circuits or windings instead of considering the fluxes due to the two windings separately. Referring to Fig. 21, let ϕ_r represent that portion of the resultant flux due to the currents i_1 and i_2 in the two windings 1 and 2, and let ϕ_1 represent that part of the total flux which links 1 only and ϕ_2 that part of the total flux which links 2 only. Let λ_1 be the linkages between ϕ_1 and circuit 1 and λ_2 be the linkages between ϕ_2 and circuit 2. Then

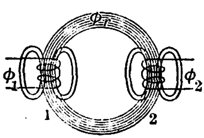

Fig. 21.

$$L_1' = \frac{\lambda_1}{i_1} \quad \text{and} \quad L_2' = \frac{\lambda_2}{i_2},$$

are called the "leakage inductances" of the two windings respectively: the reluctance of the paths of ϕ_1 and ϕ_2 are practically constant since the air portion of these paths forms a greater part of the reluctance in each case.

Let i_1 be the current in winding 1 and i_2 be the current in winding 2 in the *opposite* direction to i_1 (this is the actual relation in a transformer during most of the time) and let e_1 be the impressed e.m.f. across the terminals of the first or primary winding and e_2 the terminal e.m.f. at the terminals of the second or secondary winding when the current i_2 is flowing. Then

$$\left.\begin{aligned} e_1 &= r_1 i_1 + L_1'\frac{di_1}{dt} + N_1\frac{d\phi_r}{dt} \\ e_2 &= N_2\frac{d\phi_r}{dt} - r_2 i_2 - L_2'\frac{di_2}{dt} \end{aligned}\right\} \qquad (47)$$

where r_1 and r_2 are the resistances of the two windings and N_1 and N_2 are the number of turns in the two windings respectively.

Comparing equation (47) with (46) and noting that $e_1 = v_1$ and $e_2 = -v_2$, and i_2 in (47) is taken in the opposite direction from i_2 in (46), it may be shown that*

$$L_1' = L_1 - \frac{N_1}{N_2} M,$$

$$L_2' = L_2 - \frac{N_2}{N_1} M.$$

Whence the leakage inductance of each winding is very much less than the total self-inductance of that winding.

Fundamental Equations of the Transformer. — Comparing equations (47) and (46) it may also be seen that*

$$\phi_r = \frac{M}{N_2}\left(i_1 - \frac{N_2}{N_1} i_2\right).$$

Put $i_2' = \frac{N_2}{N_1} i_2$, that is, i_2' is the current which would be produced in the secondary if it had the same number of turns as the primary. The difference

$$i_m = i_1 - i_2'$$

is called the "magnetizing current," and the quantity $L_m = \frac{M}{N_2}$ may be called the magnetizing inductance. Then

$$\phi_r = L_m i_m.$$

In the above deduction no account is taken of the eddy-current and hysteresis loss in the iron core; these losses (the eddy-current loss in particular) may be looked upon as due to a third current i_3 flowing in a single turn short-circuited on itself and having a resistance r_3 and negligible inductance. The equation for this tertiary circuit is then

$$0 = \frac{d\phi_r}{dt} - r_3 i_3.$$

Whence the corresponding current in the primary winding is $i_3' = \frac{i_3}{N_1}$, which may also be written

$$i_3' = g N_1 \frac{d\phi_r}{dt},$$

where $g = \frac{1}{r_3 N_1^2}$ is called the "leakage conductance" of the transformer. The total primary current is then

$$i_1 = i_2' + i_m + i_3'.$$

From equation (47) and the relations given in the last two paragraphs the complete theory of the transformer may be developed.

ENERGY OF THE MAGNETIC FIELD. — Energy is required to establish a flow of electricity just as energy is required to set a column of water in motion, this "energy of motion" of electricity being analogous to the kinetic energy of a moving body. This energy of motion is most conveniently ex-

* In this equation i_1 and i_2 are taken in the opposite direction.

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

pressed in terms of the magnetic field which accompanies the flow of electricity or electric current; the mathematical expression for it may be put into various forms.

Magnetic Energy of Single Electric Circuit, Permeability Constant.—For example, consider a single electric circuit and the magnetic field which is established around this circuit when the current in it increases from zero to a value I. If at any instant the current has the value i and number of magnetic linkages between this current and its own flux at this instant is λ, then when the current increases by di the linkages increase by an amount $d\lambda$ in the right-handed screw direction with respect to the current and therefore the *electric output* of the circuit during this change is, from equation (31a), $id\lambda$, which is also equal to the *magnetic* power *input* into the magnetic circuit which it links. Hence the total energy input into the magnetic circuit or magnetic field is

$$W = \int_0^I id\lambda = \int_0^I Li\,di,$$

since by definition $d\lambda = L\,di$, see equation (42). When the permeability is constant L is also constant, whence for constant permeability

$$W = \frac{1}{2} LI^2. \tag{48}$$

Equation may also be written

$$W = \frac{1}{2}\lambda I = \frac{1}{8\pi}\frac{\mathfrak{F}^2}{\mathcal{R}} = \frac{1}{8\pi}\mathcal{R}\phi^2 \tag{48a}$$

where $\mathfrak{F}$ is the magnetomotive force ($= 4\pi NI$ when the coil has N turns in a concentrated winding), $\mathcal{R}$ is the reluctance of the magnetic circuit and ϕ the total magnetic flux.

Since the impressed m.m.f. per unit length of a magnetic flux line is equal to the magnetizing force H, and the flux per unit area perpendicular to this flux line is equal to the flux density B, the *energy per unit volume* of the magnetic field is

$$w = \frac{HB}{8\pi} = \frac{\mu H^2}{8\pi} = \frac{B^2}{8\pi\mu}. \tag{48b}$$

These various formulas should be compared with the corresponding formulas, equation (26), for electrostatic energy.

Magnetic Energy of Two or More Electric Circuits, Permeability Constant.—It can also be readily shown that the total energy required to establish currents I_1, I_2, etc. in several electric circuits linking one or more magnetic circuits of *constant* reluctance is

$$\begin{aligned} W = {} & \tfrac{1}{2} L_1I_1^2 + \tfrac{1}{2} L_2I_2^2 + \tfrac{1}{2} L_3I_3^2 + \ldots \\ & + M_{12}I_1I_2 + M_{13}I_1I_3 + M_{23}I_2I_3 + \ldots \end{aligned} \tag{49}$$

where the L's and M's represent the self and mutual inductances respectively. This may also be written

$$W = \frac{1}{2}\Sigma\phi I, \tag{49a}$$

where the summation is an *algebraic* one and includes every complete *turn* of the electric circuit, I being the current in this turn and ϕ the magnetic flux linking this turn in the *right-handed* screw direction with respect to the current.

NOTE.—ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

The energy per unit volume at any point in the magnetic field due to any number of electric circuits is represented by equation (48b), where H and B are taken as the resultant magnetizing force and flux density respectively at this point.

When the permeability is not constant the *energy transferred to unit volume* of the magnetic field due to any number of currents is

$$w = \frac{1}{4\pi}\int_0^B H\,dB \qquad (50)$$

provided the magnetizing force H and the flux density B are either in the same or directly opposite directions, as, for example, in the case of a uniformly magnetized iron toroid. To integrate this expression requires a knowledge of the relation between B and H. Note also that, due to the phenomenon of magnetic hysteresis, part of the energy required to establish a magnetic field in iron or other magnetic substance is dissipated as heat and is not recoverable when the field disappears; therefore, only part of the energy represented by this formula is "stored" in the field in a recoverable form. See article on *Magnetic Properties of Iron.*

MECHANICAL FORCES IN THE MAGNETIC FIELD. (*See also article on Electromagnets.*) — Experience shows that all bodies in which an electric current exists, and all bodies in which a magnetic flux exists, exert in general mutual mechanical forces upon one another tending to produce such a relative motion of these bodies as will *increase* the energy of the magnetic field. Let f be the component of the force tending to move any body in the field in a given direction and let dW be the increase in the energy of the field due to displacing the body a distance dx in this direction, then

$$f = \frac{dW}{dx}, \qquad (51)$$

provided this displacement does not alter the existing magnetomotive forces in the field.

Similarly, calling T the component of the torque tending to turn any body in the field about a given axis, and dW the *increase* in the magnetic energy due to the turning of the body through an angle of $d\alpha$ radians about this axis, then

$$T = \frac{dW}{d\alpha}, \qquad (51a)$$

provided this displacement does not alter the existing magnetomotive forces in the field.

Equations (51) and (51a) also give the actual force and torque respectively during a change in position which *does* cause a change in the magnetomotive forces in the field, provided dW is taken to represent the net increase in the energy of the field. This force and torque may differ greatly from the steady state force and torque; see article on *Electromagnets.*

Force Produced by a Magnetic Field on a Coil Carrying a Current. — From equation (32) the energy *output* of an electric circuit, when the magnetic flux threading it in the right-handed screw direction with respect to the current in it increases by an amount $d\phi$, is $dW = NI\,d\phi$, where N is the number of turns linked by this increase in flux and I is the current in each turn. This is the energy *input* into the magnetic field. Whence if an increase in flux $d\phi$ is

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

produced through the coil when it moves a distance dx, the force acting on the coil in the direction of dx is

$$f = NI\frac{d\phi}{dx}; \tag{52}$$

$d\phi$ represents the increase in the flux linking the coil in the *right-handed* screw direction with respect to the current in it or the number of flux lines which cut the coil as the result of its motion. Similarly, when the coil is so mounted that it can move only about a fixed axis, then the value of the torque tending to turn it about this axis is

$$T = NI\frac{d\phi}{d\alpha}, \tag{52a}$$

where $d\phi$ represents the increase in the flux linking the coil in the right-handed screw direction with respect to the current in it when the coil turns through an angle α (in radians).

From these relations it follows that a coil carrying an electric current, when in the magnetic field due to any other agent (current or permanent magnet), always tends to take up that position in which it will embrace the maximum possible flux linking the coil in the right-handed screw direction with respect to the current in it. This accounts for the attraction of two parallel coils when they carry currents in the same direction, and the repulsion of two such coils when they carry currents in opposite directions. This principle is useful in determining the direction of motion of the moving element in such devices as the electric motor, galvanometer, current balance, electrodynamometer (q.v.).

Torque on the Coil When its Plane is Parallel to the Magnetic Field. — When the coil is placed with its plane parallel to the flux lines due to some other agent (e.g., a permanent magnet or another coil carrying a current), the flux linking the coil due to this agent is zero; see Fig. 22. Let the two circles represent sections of the two sides of the coil, its plane being perpendicular to the page, and let the dot in the left-hand circle indicate that the current is up through this side of the coil and the cross in the other circle that it is down through the other side. Let B be the flux density of the field constant for each point along the flux line since the flux lines are parallel, and let A be the area of the coil and let $\phi = BA$, that is, ϕ represents the total flux which *would be produced* through the coil by a uniform field of flux density B at *right angles* to it. Then the torque on the coil when its plane is *parallel* to the field is

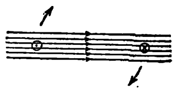

Fig. 22.

$$T = N\phi I. \tag{53}$$

This relation is useful in calculating the torque on the moving element of a galvanometer, ammeter, electrodynamometer, wattmeter, etc.

Average Torque on a Coil Rotating in a Magnetic Field. — Consider a coil which is rotating with an angular velocity ω about a fixed axis in a magnetic field due to some other agent (e.g., an armature coil rotating in the magnetic field produced by the current in the field coils). Let the current in this coil be constant and in the same direction with respect to the coil while the coil turns from the position in which it embraces the maximum flux ϕ in the left-handed screw direction to the position (a half revolution in a 2-pole machine) when it embraces this same maximum flux ϕ in the right-handed

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

screw direction. The total change in the flux while the coil turns through this angle, π radians in the case of a 2-pole machine, is 2ϕ, whence the average torque turning the coil through this half revolution is

$$T = \frac{2N}{\pi} I\phi \cdot \tag{54}$$

That is, the average torque is proportional to the product of the current by the total flux per pole. When a commutator is provided to change the direction of the current every half turn, then the torque is in the same direction for a complete turn. See *Motors*.

When the coil is mounted in a slotted iron core which rotates with the coil as in an ordinary motor, this torque is exerted partly on the wire and partly on the teeth of the core.

Force on a Wire in a Magnetic Field. — Consider a wire of length l forming part of a closed circuit, Fig. 23. Let B be the value of the flux density at the wire, I be the current in the direction indicated, and let the lines representing the flux be perpendicular to the wire in the direction from the eye to the page. When this wire moves a distance dx to the left the flux threading the closed loop formed by the circuit is increased by an amount $d\phi = Bldx$, whence the force acting on the wire is, from equation (51),

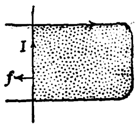

Fig. 23.

$$f = BlI. \tag{55}$$

Left-hand Rule. — The relative directions of this force, the flux density B and the current I may be conveniently determined by pointing the forefinger of the left hand in the direction of the flux and the middle finger in the direction of the current (I), then if the thumb is held perpendicular to these two fingers it will point in the direction in which the force tends to move the wire. Compare with the right-handed rule for e.m.f.

Forces on Magnetic Bodies in a Magnetic Field. — In general the reluctance of a magnetic field to the flux set up by a given magnetomotive force depends upon the relative positions of the various magnetic bodies in the field with respect to one another and with respect to the electric circuit producing this m.m.f. When any magnetic body in the field is displaced the total reluctance will in general be changed due chiefly to the change in the dimensions of the air portion of the circuit. From equations (48a) and (51) it can be shown that the force acting on any magnetic body in the field is in the direction of the flux lines threading it and has the value

$$f = -\frac{1}{8\pi}\phi^2 \frac{d\mathcal{R}}{dx}, \tag{56}$$

provided the magnetomotive force remains constant; where ϕ represents the total flux threading the body and $d\mathcal{R}$ represents the *increase* in the reluctance of the magnetic circuit corresponding to a displacement dx of the body in the direction of the flux lines. The minus sign in this formula indicates that the force is always in the direction in which a motion of the body would *decrease* the reluctance of the circuit. In deducing this expression it is assumed that the permeability of each body in the field is constant. It can also be shown that to a close approximation the same formula holds for actual magnetic bodies, for which the permeability is not a constant.

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

The above relation accounts for the attraction of one magnet for another when their unlike poles are nearer each other than their like poles, and the repulsion of two magnets when their like poles are nearer than their unlike poles. It also accounts for the attraction of iron or other paramagnetic substance by *either* pole of a magnet or by either "face" of an electric circuit, and the repulsion of a diamagnetic substance by either pole of a magnet or either face of an electric circuit; see article on *Electromagnets*.

As a special application of equation (56) consider the electromagnet shown in Fig. 24, which is one form of "permeameter" (q.v.). R is a rod of iron the flat end P of which makes contact with the yoke Y. This rod passes through a hole in the top of the yoke. C is a magnetizing coil. The flux lines through the rod are uniformly distributed and pass perpendicularly into the yoke at the joint P. Let A be the area of the end of the rod and let B be the flux density at this area. When the rod is raised a distance dx, so that an air gap of length dx is formed at P, an increase in the reluctance of the magnetic circuit is produced due to the formation of an air gap at P, and a decrease in reluctance is produced by the shortening of the iron part of the circuit, i.e., by the reluctance of a length dx of the rod. Due to the high permeability of the iron compared with that of the air, the decrease in the reluctance of the iron part of the circuit may be neglected in comparison with the increase in reluctance due to the formation of the air gap. The net increase in reluctance may then be taken as the reluctance of this air gap of length dx, that is, $d\mathcal{R} = dx/A$, since the permeability of air is unity. Whence, from equation (56), the force required to raise the rod is

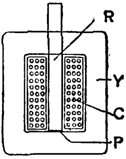

Fig. 24.

$$f = \frac{1}{8\pi}\frac{\phi^2}{A} = \frac{B^2A}{8\pi}. \tag{56a}$$

That is, the tractive force per unit area between the rod and the yoke is proportional to the square of the flux density in the rod.

HYPOTHESIS REGARDING THE NATURE OF MAGNETISM. — The peculiar properties possessed by a magnetic needle or other magnet may be accounted for by assuming that at least some of the molecular charges in a magnetic substance have an orbital motion without friction, forming a kind of "molecular solar system." The magnetization of such a substance is then due to the setting of the molecular currents in planes more or less parallel to the plane of the magnetizing current. In the case of a permanent magnet these molecular currents retain their parallel or "polarized" condition even when the magnetizing current is removed. For example, when a needle is magnetized by a current in a coil placed around it, the molecular currents are set at right angles to the axis of the needle. A magnetic needle placed in a magnetic field, therefore, tends to set itself so that each molecular current embraces maximum flux and hence "points" in the direction of this flux.

NOTE. — ALL FORMULAS ON THIS PAGE ARE IN C.G.S. ELECTROMAGNETIC UNITS.

ELECTROCHEMICAL PROCESSES, INDUSTRIAL. — (*See also Electrochemistry, Principles of; Furnaces, Electric.*) The principal industrial electrochemical processes are the following :

Electroplating,
Galvanoplasty, including electrotyping,
Electrolytic refining of metals,
Electrolytic winning of metals,
Electrolytic oxidation and reduction,
Electrolysis of sodium and potassium in chloride solutions; electrolysis of water,
Electric-furnace processes (*see Furnaces, Electric*),
Production of ozone.

Some of the more important of these various processes are briefly described below.

ELECTROPLATING. — Electroplating consists in covering a conducting surface (usually metallic) with a thin, smooth, compact, well-adhering layer of metal, by depositing this metal electrolytically from an aqueous solution of one of its salts. The anode of the electroplating vat consists of rods or plates of the same metal as that of the salt in solution and is connected to the positive terminal of the source of electricity. The object to be plated forms the cathode, and is connected to the negative terminal. The anode dissolves approximately to the same extent that the cathode gains, so that the amount of the metal ions in the bath remains nearly constant.

Suspension of Objects to be Plated. — The cathodes are always suspended in the bath between two rows of anodes, so that they will be plated uniformly on both sides. When the cathode is of irregular shape, or very large, it must be turned frequently during the plating in order to get a uniform deposit. The cathodes and anodes are suspended by copper wires from horizontal metallic tubes, the ends of which rest on the edge of the plating vat. The metallic tubes are permanently connected to the source of the electricity, so that as soon as the cathodes are suspended in the bath, electrolysis begins. Small objects, such as tacks, pins and screws, are suspended in the vat in a wire basket, which is, of course, plated simultaneously. To get a uniform plated surface the objects should be well shaken during electrolysis. The anodes are removed from the bath only when they are nearly used up and have to be replaced.

Construction of Vats. — Large plating vats are made of wood lined with some specially prepared substance resembling pitch, or with lead. Small tanks for silver or gold plating are usually porcelain lined.

Voltage and Current Density. — Electroplating tanks are always connected in parallel, so that they will be electrically independent of each other.

Low-voltage generators of from 5 to 6 volts are, therefore, used in plating, and each tank must be connected directly to the generator through a regulating rheostat in order to regulate the voltage.

The proper current density in any plating process is that density at which a good deposit is formed. This may vary within certain limits for a given solution and temperature; it is a function of the temperature and the nature of the solution.

Washing and Pickling. — In order to make the metal adhere well to the surface to be plated, the surface must be smooth and perfectly clean. It is first polished, and the grease is then removed by dipping it into a hot alkaline bath containing 10 per cent, by weight, of sodium carbonate or sodium hydrate.

After washing off the alkali, the object is dipped into a bath called a "pickle," the purpose of which is to remove any oxide that may have been produced by the alkali, and to give a bright surface. The pickle is then washed off with water and the object is suspended immediately in the electroplating vat.

Pickling Solutions. — The pickle varies with the nature of the metal treated. Cast iron and wrought iron are pickled in a solution consisting of 15 parts, by weight, of water to 1 part of concentrated sulphuric acid. A suitable pickle for zinc is dilute sulphuric or hydrochloric acid. Copper, brass, bronze and German silver are pickled first in a bath consisting of 200 parts, by weight, of nitric acid of specific gravity 1.33, 1 part of common salt and 1 part of lampblack. The lampblack is intended to form some nitrous acid from the nitric acid. The object is then washed in boiling water and is immersed in a "bright dipping bath," to give a bright surface. This bath consists of 75 parts, by weight, of nitric acid of specific gravity 1.38, 100 parts of concentrated sulphuric acid and 1 part of common salt.

After the plating is finished, the object is removed from the plating bath, washed in hot water and placed in warm sawdust to dry.

Plating by Dipping. — A thin film of metal may be deposited on a metal by dipping it into a solution of a salt of a metal which is electronegative (*see Electrochemistry, Principles of*) with respect to the metal to be plated, e.g., by dipping iron into a copper-sulphate solution. A small amount of iron dissolves and an equivalent amount of copper is deposited on the remaining iron. Of course, only a thin film can be produced in this way, for, as soon as the iron is covered with copper, the action ceases. No external electric current is needed in this process.

Plating by Contact. — When the metal to be plated is electronegative with respect to the metal to be deposited on it, the electro-deposition can be obtained by connecting the former to a zinc rod. In this case, the solution must be of a complex salt, in order to reduce the deposition of the metal in solution on the zinc itself. For example, silver may be deposited on copper by connecting a zinc rod or plate to the copper object by a wire and dipping both into a potassium-silver-cyanide solution; the zinc dissolves and silver is deposited on the copper, while some silver is also deposited on the zinc. No external current is needed in this process.

Nickel Plating. — The solution ordinarily used consists of 50 parts, by weight, of the double nickel-ammonium sulphate, $NiSO_4 \cdot (NH_4)_2SO_4 \cdot 6\,H_2O$ with from 25 to 50 parts of ammonium sulphate to 1000 parts of water. The anodes are nickel. The solution is made acid enough to redden litmus slightly, either by addition of a small amount of sulphuric acid or one-half per cent of citric acid. The proper current density on the cathode is about 0.6 ampere per square decimeter (5.5 amperes per square foot) of exposed surface, which requires about 2 volts. The surface should be perceptibly coated with nickel in two or three minutes, and a few bubbles of hydrogen are liberated continuously. If the current is too weak, the surface becomes discolored, and if too strong hydrogen is evolved more rapidly and the surface turns dark.

Iron is sometimes copper plated before it is nickel plated, but this is not necessary, for nickel adheres to iron perfectly well if the surface has been properly cleaned.

A nickel-chloride solution gives good results in plating any metal except iron. Iron always eventually rusts if plated in a chloride bath.

Copper Plating. — The metals on which copper is usually plated, such as zinc, iron and tin, are more electropositive than copper. On dipping any of these metals into an acid copper-sulphate bath, they would become covered with a layer of copper, which in some cases is spongy and does not adhere

well. In order to reduce the velocity with which this reaction takes place a solution of the double cyanide of copper and potassium, $KCu(CN)_2$ is used. This can be made by dissolving cuprous cyanide in potassium cyanide to form a 3 to 8 per cent solution,* with an excess of 0.2 per cent of potassium cyanide. This bath is generally heated to 50° or 60° C. The proper current density at the cathode is about 0.5 ampere per square decimeter (4.6 amperes per square foot) which requires about 3 volts at room temperature.

Surfaces that have already received a thin coating of copper in a cyanide bath are sometimes thickened in an acid copper-sulphate bath. The cyanide must be washed off on transferring to the sulphate bath. A sulphate bath may be made by dissolving 150 grams of copper sulphate $CuSO_4 \cdot 5\,H_2O$ and 50 grams of concentrated sulphuric acid in 1 liter of water. The proper current density is about 0.7 ampere per square decimeter (6.5 amperes per square foot) which requires less than 1 volt.

Small springs are very much weakened by copper plating in a cyanide bath, and are very likely to break while suspended, slightly stretched, in the bath during plating. The reason for this is not known.

Zinc Plating. — Electrolytically deposited zinc is of a dull color and is not as pleasing in appearance as layers obtained by dipping in melted zinc, but electrolytic zinc has been shown to protect iron better for a given thickness of deposit than a coating made from melted zinc. (*Burgess, Electrochem. and Met. Ind., Vol. 3, p. 17, 1905.*) A suitable solution consists of 200 grams of zinc sulphate, $ZnSO_4 \cdot 7\,H_2O$, 40 grams of sodium sulphate, $Na_2SO_4 \cdot 10\,H_2O$ and 10 grams of zinc chloride per liter, slightly acidified with sulphuric acid. The current density in the cathode is from 0.5 to 2 amperes per square decimeter (4.6 to 18 amperes per square foot) which requires from about 1 to 2.5 volts. Zinc anodes are used. A little more zinc is dissolved than is deposited, due to the free acid. The acid must be replaced as it is used up. The resistance may be reduced by warming the bath to 40° or 45° C.

Brass Plating. — If an acid solution of zinc and of copper sulphates were electrolyzed, only copper would be deposited. In a cyanide solution of zinc and copper, however, these metals are deposited simultaneously in the form of an alloy. (*Spitzer, Zeit. f. Electrochemie, Vol. 11, p. 367, 1905.*) The copper is deposited more easily than the zinc, so that at a low current density, 0.1 ampere per square decimeter (0.93 ampere per square foot), only a small amount of zinc is deposited, but at 0.3 ampere per square decimeter (2.8 amperes per square foot), the deposit contains only 80 per cent of copper. Increasing the current density above this amount changes the composition of the deposit only slightly.

A suitable bath for brass plating is made by substituting zinc cyanide for half of the copper cyanide in the solution given above for plating. Brass anodes are used.

Other brass baths that have been found to give good deposits are the following:

1 liter water,
14 grams sodium carbonate, dried,
20 grams sodium sulphate, dried,
20 grams double cyanide of potassium and copper,
20 grams monosodium sulphite,
20 grams double cyanide of potassium and zinc,
1 gram potassium cyanide,
2 grams ammonium chloride.

* An *n* per cent solution of a substance contains *n* parts, by weight, of that substance in 100 parts, by weight, of the solution.

With the electrodes 15 centimeters apart, current density 0.3 ampere per square decimeter (2.78 amperes per square foot) about 3 volts are required.

1 liter water,
15 grams double cyanide of potassium and copper, crystallized,
16.5 grams double cyanide of potassium and zinc,
25.0 grams sodium sulphite,
2.0 grams potassium cyanide, 98 per cent.

Current density 0.3 ampere per square decimeter (2.78 amperes per square foot) requiring 3 volts when the electrodes are 10 centimeters apart. (*Schlötter, Galvanostegie, 1. Teil, p. 238, 1910.*)

Silver Plating. — The double cyanide of potassium and silver is universally used for silver plating on account of the smooth deposit obtained with this solution. The deposit from a nitrate comes down in the form of isolated crystals, which do not cover the surface completely. The solution contains from 1 to 5 per cent silver as potassium-silver cyanide, $KAg(CN)_2$, with 0.5 per cent of free potassium cyanide. Too much or too little free cyanide gives a bad color to the deposit. A good silver plating bath may be made up as follows:

20 grams potassium silver cyanide,
10–12 grams potassium cyanide, 99 per cent,
1 liter water.

The current density is 0.3 ampere per square decimeter, at about 1 volt. (*Schlötter, Galvanostegie, 1. Teil. p. 149, 1910.*) The anodes are silver.

Silver is deposited only on a surface of copper or copper alloy. Other metals must be copper plated before silvering. In order to make the silver adhere well, the copper surface must be amalgamated by dipping the cleaned surface in a "quicking bath," consisting of a solution of 30 grams of potassium-mercury cyanide, $KHg(CN)_3$, and 30 grams of potassium cyanide in 1 liter of water. On removal from the quicking bath, articles are washed and placed immediately in the silvering bath.

Gold Plating. — The solution used in gold plating contains from 0.35 to 1 per cent of gold as the double cyanide of gold and potassium, $KAu(CN)_2$, with twice as much free potassium cyanide. The current density on the cathode is about 0.2 ampere per square decimeter (1.9 amperes per square foot), which requires about 1.5 volts. The anodes are pure gold. The solution may be used hot or cold. The deposit from a hot solution is more dense, more uniform and of a richer color. The color of the gold deposit may be influenced by simultaneously depositing some other metal. Green gilding may be obtained by adding a little silver cyanide to the bath, until the desired tint is obtained. The solution should be cold. To give the deposit a red tint, a little copper cyanide is added to the solution.

Other Plating Processes. — Plating with the following metals is sometimes carried out: platinum, tin, lead, iron, antimony, and arsenic.

Plating on Aluminum frequently does not wear well, on account of the difficulty in getting a perfectly clean aluminum surface on which to plate. This is due to the rapidity with which a thin invisible film of oxide or hydroxide forms on aluminum when exposed to the air or to any solution. One method of overcoming this difficulty is to immerse the aluminum in a solution of potassium hydrate until hydrogen is evolved, and then dip without previous washing in a potassium-silver-cyanide solution. The aluminum is immediately covered with a layer of silver. It is still better to amalgamate by dipping into a 0.5 per cent solution of mercuric chloride immediately after treating with hydrate. The chloride is rinsed off, and the object again treated with potassium hydrate and

then immediately suspended in the silvering bath. (*Langbein, Electrodeposition of Metals, 4th ed., p. 409, 1902.*)

Burgess (*Electrochem. Ind., Vol. 2, p. 85, 1904*) recommends cleaning first with dilute hydrofluoric acid, then with a mixture of 100 parts of sulphuric acid and 75 parts of nitric acid, both concentrated. After rinsing with water the surface is immediately plated with zinc, as this metal is found to adhere better than many others. Starting with the zinc surface, other metals are readily deposited.

GALVANOPLASTY. — Galvanoplasty is the art of reproducing by electrolysis articles of various kinds, or of making finished products, such as set-up type, copper tubes, etc.

Electrotyping. — The object is to make a copper plate which shall be an exact duplicate of type which has been set up ready for printing. First an impression of the type is made in wax, which is then covered with a thin layer of graphite, by dusting the fine powder over the wax surface with soft brushes. A thin layer of copper is then formed by sprinkling the surface with iron filings and pouring over the surface a solution of copper sulphate. The iron goes into solution, depositing copper on itself and on the graphite. The wax plate is then washed in water and suspended in an acid bath of copper sulphate, where copper is deposited electrolytically until a thin sheet that can be stripped from the wax has been formed. After removing the copper sheet from the wax plate, a melted lead-antimony alloy is poured on its reverse side, making a plate approximately 0.5 inch thick. This is then used for printing in place of the original type. The economy of this procedure comes in the saving of wear on the type, and the relatively small amount of type which has to be kept in stock.

The current density ranges from 1 to 2 amperes per square decimeter (0.9 to 1.8 amperes per square foot) and the volts per cell from 0.75 to 1.5.

Copper tubes are made by the Elmore process by depositing copper on a conducting cylinder which rotates in an acid copper-sulphate bath. The surface must be conducting, but the copper must not stick so firmly that the cylinder cannot be slipped out of the tube when finished. In order to keep the outer surface of the tube smooth, it is frequently polished during the deposition of copper. Copper sheets may be made by making tubes of large diameter and cutting them open.

Metallic foil may be made by the electrolytic deposition of a thin metallic layer on a surface from which it can be removed.

Parabolic mirrors are made by depositing copper electrolytically on a parabolic glass surface that has been silvered, and separating the metal from the glass by warming. (*Cowper-Cowles, Electrolytisches Verfahren zur Herstellung parabolischer Spiegel, 1904.*)

ELECTROLYTIC REFINING. — The method of refining metals electrolytically is as follows. The impure metal is made the anode of an electrolytic bath, the electrolyte of which is, at the start, a solution of a pure salt of the metal to be refined, and the cathode is a sheet of the refined metal. On passing the current, metal dissolves, along with certain of the impurities. The impurities which are electropositive with respect to the principal metal dissolve; those electronegative with respect to the principal metal remain adhering to the anode. When the latter finally drop from the anode they may be dissolved by the free acid, in which case they would be precipitated again on coming in contact with the anode or the cathode. Some metals are precipitated as an insoluble salt as soon as they dissolve, and are thus removed from the further action of the current.

When it goes into solution, the principal metal is, therefore, separated from those metals which are electronegative with respect to it. When it is deposited

on the cathode, it is separated from those metals which are electropositive with respect to it. The bath thus becomes contaminated with certain of the impurities in the anode, and these would eventually be deposited on the cathode if the bath is not purified from time to time.

Anode Mud. — The metals which do not dissolve drop to the bottom of the tank forming the "anode mud." It is from this mud that the platinum, gold and silver are recovered in copper refining. For methods of working up anode mud, see Kern, *Met. and Chem. Eng.*, Vol. 9, p. 417, 1911.

Copper Refining. — The object in refining copper electrolytically is to obtain as pure copper as possible for electric conductors and to obtain the precious metals contained in the crude copper. A representative composition of crude copper anodes for American refineries is the following (*Addicks, Electrochem. Met. Ind., Vol. 4, p. 16, 1906*):

Copper	98–99.5 per cent.
Silver	0–300 oz. per ton.
Gold	0–40 oz. per ton.
Arsenic	0–2 per cent.

The refined copper is about 99.95 per cent copper. The electrolyte is a solution of copper sulphate and sulphuric acid containing from 4 to 10 per cent of free acid and from 12 to 20 per cent of copper sulphate. The current density ranges from 0.43 to 4.8 amperes per square decimeter (4 to 45 amperes per square foot) of cathode surface and the volts per cell range from 0.1 to 0.3. (*Ulke, Die Elektrolytische Raffination des Kupfers, p. 42, 1904.*) The electrolyte circulates slowly from tank to tank. The cathodes are thin sheets of refined copper.

Multiple and Series Systems of Arranging the Electrodes. — The tanks for holding the solution and electrodes are made of wood and are frequently lined with lead. There are two methods of arranging the electrodes. In the "multiple system" all the cathodes of one tank are connected, and likewise the anodes, the cathodes having an anode on each side, as shown in Fig. 1.

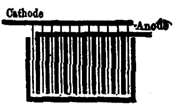

Fig. 1. Multiple System

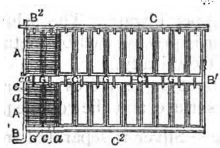

Fig. 2. Walker Multiple System

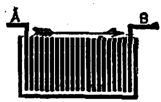

Fig. 3. Series System

The most economical method as regards the use of copper of connecting tanks in the multiple system with each other is that devised by Walker (*U. S. Pat. 687, 800, 1901*). In this system the current flows from tank to tank without being collected in a single bus bar in this passage. The *cathodes* of the first tank rest on a conducting bar *G* (Fig. 2) on which the *anodes* of the second tank also rest. The figure shows two series of tanks with a leading in bus bar *B*, bus bar *B′* connecting the two series, and leading out bus bar B^2.

In the Hayden or "series system," the electrodes are arranged as shown in Fig. 3. The impure copper plates are suspended in the solution at equal distances apart, only the end ones being connected to the dynamo. The current enters at the electrode *A*, which dissolves, and on flowing through the tank passes through the intermediate plates. Pure copper is deposited on the sides of the plates facing *A*, and dissolved from the opposite surfaces facing *B*. Some

conducting preparation is painted over the sides of the intermediate electrodes facing *A*, so that the copper deposited can be separated from the impure copper. When a certain amount of the impure copper has been dissolved, the electrodes are removed, the pure copper is separated from the impure, and the latter is melted and cast into new electrodes. For further details, see Ulke, *Die Elektrolytische Raffination des Kupfers*, 1904.

Comparison of the Two Systems. — The energy required in the series system is about 70 per cent of that required in the multiple system. Contacts give more trouble in the multiple than in the series system. The electrodes in the series system cost more to prepare than in the multiple system. The investment in a series plant of given capacity is less than in a multiple plant. Since lead-lined tanks cannot be used in the series system, the maintenance expense of a series plant is greater than that of a multiple plant.

Nickel Refining. — Nickel may be refined by using a weakly acid solution of nickel chloride or nickel sulphate. To get thick deposits the solution must be heated to from 50° to 90° C. (*Foerster, Zeit. f. Elektroch., Vol. 4, p. 160, 1897*). Nickel and copper may be separated by the David H. Brown process, in which nickel is separated from an alloy of nickel and copper, by depositing the nickel electrolytically. Very pure nickel required for special purposes is refined electrolytically by the Orford Copper Company, by a secret process. (*Electrochem. and Met. Ind., Vol. 4, p. 26, 1906.*) Foerster obtained good results with a current density of 0.5 to 2.5 amperes per square decimeter (4.5 to 23 amperes per square foot) between 50° C. and 90° C. The neutral nickel-sulphate solution contained 30 grams of nickel per liter. Günther obtained good deposits at 60° to 65° C., with 4 to 5 amperes per square decimeter (37 to 45 amperes per square foot) at 3.5 to 4 volts, with nickel sulphate baths. (*Borchers, Elektrometallurgie des Nickels, 1903.*)

Silver Refining. — Two cases arise, (1) the separation of silver from copper in an alloy consisting mainly of these two metals, and (2) the separation of silver from relatively small amounts of gold and platinum.

Dietzel Process. — One method of separating silver and copper is the Dietzel process. This consists in dissolving both of the metals as anode in a weakly acid solution of copper nitrate. The solution is then transferred to another vessel and the silver is precipitated by metallic copper, following which the copper is deposited electrolytically.

The current density is about 1.5 amperes per square decimeter (14 amperes per square foot) of cathode surface, and the voltage per cell from 2.5 to 3.5 volts.

Moebius Process. — Silver is separated from small amounts of other metals by the Moebius process. In this process the anodes consist of the impure silver, the cathodes of thin sheet silver, and the electrolyte is a slightly acid dilute silver-nitrate solution. In the earlier type of apparatus the cathodes were stationary; in the later type the cathode is a rotating sheet of silver. In both the pure silver is scraped off as crystals.

The current density is about 3 amperes per square decimeter (28 amperes per square foot) of cathode surface, and the voltage per cell from 1.4 to 1.5 volts.

Gold refining is carried out in a slightly acid solution of gold chloride. Gold anodes do not dissolve in a solution of gold chloride $AuCl_3$, or of chloroauric acid $HAuCl_4$, but the chlorine liberated comes off in the gaseous form. If some free alkali chloride or hydrochloric acid is present, the gold dissolves. The resulting gold is never less than 999.8 fine, and frequently is 1000 fine.

The baths contain about 3 per cent of free hydrochloric acid with 30 to 40 grams of gold as chloroauric acid per liter. The bath is heated to 60° or 70° C.,

and the current density is about 10 amperes per square decimeter (93 amperes per square foot) at about 1 volt.

Lead refining is carried out by the Betts process. The electrolyte is a solution of lead fluosilicate ($PbSiF_6$) containing 60 to 70 grams of lead and 120 to 130 grams of SiF_6 per liter, and 0.1 per cent of glue. The object in refining lead is to recover the copper, antimony, bismuth, gold and silver. Tin cannot be separated from the lead electrolytically, on account of its proximity to lead in the electrolytic series. (*See article on Electrochemistry, Principles of, and Lead Refining by Electrolysis by A. G. Betts, 1908.*)

The current density ranges from 1.3 to 1.7 amperes per square decimeter (12 to 16 amperes per square foot) of cathode surface, and the voltage per cell from 0.30 to 0.38 volts.

According to Duisberg (*Journ. of Ind. and Eng. Chem. for 1912, p. 752*) iron is now refined electrolytically by the firm Langbein-Pfanhauser & Co., Leipzig. It has valuable magnetic properties, and is used in electromotors. The electrolysis is carried out at 100° to 120° C., but the current density and voltage are not given.

Refining of Other Metals. — A number of other metals may be refined electrolytically, such as mercury, tin, bismuth, and antimony, but these are relatively unimportant.

ELECTROLYTIC WINNING OF METALS. — The attempts that have been made to win metals directly from their ores or from matter are based on the same principle as that underlying metal refining. These attempts have not been successful until recently, however, on account of the large amount of impurity that gets into the bath and on account of mechanical difficulties. The best known of such attempts, are the following.

Marchese Process. — In the Marchese process it was attempted to obtain pure copper from a matte containing principally copper, lead, iron and sulphur, by electrolyzing this matte as an anode in a sulphate bath. The process seemed a success at first, but finally failed.

Siemens and Halske Process. — The Siemens and Halske process for extracting copper consists in electrolyzing a solution of iron sulphate and copper sulphate in a cell in which the anode and cathode are separated by a linen diaphragm. The anode was carbon; the cathode pure copper. In the cathode compartment the solution loses copper by deposition on the cathode. The solution then circulates to the anode compartment, where the ferrous sulphate is oxidized to ferric sulphate. See below, under *Electrolytic Oxidation*. From here the solution circulates to another vat where fresh ore, consisting of copper pyrites ($Cu_2SFe_2S_3$) that has been roasted so as to change the iron sulphide to oxide, is treated. The ferric sulphate dissolves the cuprous sulphide as follows:

$$Cu_2S + 2\,Fe_2(SO_4)_3 = 2\,CuSO_4 + 4\,FeSO_4 + S.$$

This solution, enriched in copper, is then conveyed to the cathode compartment, and the cycle is completed. This process also failed when tried on a commercial scale.

Hoepfner Process. — In the Hoepfner process the copper ore, consisting of copper sulphide, is dissolved in a cupric chloride solution containing a relatively large amount of sodium chloride. The reaction is as follows:

$$Cu_2S + 2\,CuCl_2 = 2\,Cu_2Cl_2 + S.$$

The cuprous chloride, insoluble in water, is held in solution by the sodium chloride. The anode and cathode of the electrolytic cell are separated by a diaphragm. The solution first circulates to the cathode compartment, where part

of the copper is deposited, and then to the anode, where the cuprous chloride is oxidized to cupric chloride. The solution from the anode then circulates to fresh ore.

Copper Hydrometallurgy at Chuquicamata. — A process is now being perfected by the Chile Exploration Company for winning copper directly from the ore of the Chuquicamata copper mine, in Chile. The ore is dissolved in dilute sulphuric acid in leaching tanks. The solution is then conducted to the electrolyzing tanks where the copper is deposited, using insoluble magnetite anodes and their copper cathode starting sheets. The electrolytic refinery will have a capacity of 335,000 pounds of copper per day. (*E. A. Cappelen Smith, Met. & Chem. Eng., 1914, Vol. 12, pp. 291–294.*)

Salom Process. — Lead was at one time extracted from galena (PbS) by the Salom process, consisting in electrolyzing the powdered galena as cathode in sulphuric acid. The hydrogen deposited on the galena combines with the sulphur, forming hydrogen sulphide and leaving the lead as lead sponge. This process was given up, partly at least, on account of the poisonous action of the hydrogen sulphide. (*Trans. Am. Electroch. Soc. Vol. 1, p. 87, 1902; Vol. 4, p. 101, 1903.*)

Hoepfner Zinc Process. — In the winning of zinc, electrolysis may, in the future, take an important part, on account of the fact that in the ordinary metallurgical process there is a large loss. A process devised by Hoepfner consists in roasting the zinc ore if it is insoluble, dissolving the zinc, and depositing it by electrolysis, with insoluble anodes. Very little zinc is refined electrolytically, because it contains no noble metals and there is not much demand for very pure zinc.

Detinning Tin Scrap and Old Cans. — The two principal methods of recovering tin from tin scrap and old tin cans are due to Goldschmidt. The first consists in electrolytically dissolving the tin and depositing it in the metallic state; the second method, which however is not electrolytic, converts the tin into tin tetrachloride by treating with dry chlorine.

In the electrolytic method the solution consists of a sodium hydrate solution, containing a certain amount of carbonate, absorbed from the air, and sodium stannate. The best concentrations are: 10 to 12 per cent alkalinity, not over 7 per cent free alkali; carbonate not over 3 per cent; stannate not over 5 per cent. Temperature, 60° to 70° C. About one-tenth of the solution must be replaced every week.

The tin scrap is suspended in the solution in baskets (39 by 35 by 18 inches) of perforated sheet iron, containing 100 to 130 pounds of scrap. Old cans are cleaned, compressed and then cut up. The cathodes are sheet iron 39 by 35 inches. The tin dissolves from the anode and is deposited as spongy tin on the cathode. The scrap is left in the bath for three hours. The spongy tin is compressed by a hydraulic press into cylinders weighing six pounds; these are subsequently melted in a furnace with sealed tubes. This sponge contains 50 per cent tin and 50 per cent ash. The ash is subsequently reduced with carbon in an open-hearth furnace, yielding 70 per cent of the tin.

Very careful working is necessary to remove the tin so completely that the iron can be sold to open-hearth plants. Even then the iron contains 0.1 to 0.5 per cent tin.

The cathode current density is never over 0.75 ampere per square decimeter (7 amperes per square foot), at 2 to 3 volts per cell. (*Electrochem. and Met. Ind., Vol. 7, p. 79, 1909; Met. and Chem. Eng., Vol. 10, p. 202, 1912.*)

ELECTROLYTIC OXIDATION AND REDUCTION is frequently carried out on substances in solution. One of the advantages of the electrolytic

method is that no other substance has to be added to the solution. In carrying out an electrolytic oxidation or reduction a porous diaphragm is used to separate the anode and cathode compartments. The substance to be reduced is placed in the cathode compartment, where the whole or a part of the hydrogen that would be evolved by the current while in the nascent state, acts on the substance in question. The intensity of the reduction may be varied by varying the potential difference between the solution and the cathode. This is accomplished either by increasing the current density on the cathode, or by making the cathode of different metals on which the overvoltage (*see Electrochemistry, Principles of*) is different. It frequently happens that the metal composing the cathode has a marked accelerating effect on the velocity of the reduction. Thus the reduction may be much more complete on one metal than on another, though the potential difference between the metals and the solution is the same in both cases. The same considerations apply to oxidation on the anode.

Typical Reduction and Oxidation Processes. — Examples where electrolytic reduction has been found useful are: in the manufacture of white lead by corroding a lead anode in a suitable solvent, e.g., the Luckow process (*Zeit. f. Elektroch., Vol. 3, page 482, 1897*); in the preparation of the lower salts of vanadium, molybdenum and titanium. Examples where electrolytic oxidation has been employed are: in the oxidation of the lower cerium sulphate, $Ce(SO_4)$, to $Ce(SO_4)_2$, the latter being useful as an oxidizing agent; in oxidizing potassium manganate, K_2MnO_4, to permanganate, $KMnO_4$; in the oxidation of potassium ferrocyanide, $K_4Fe(CN)_6$, to the ferricyanide, $K_3Fe(CN)_6$; and of chromium sulphate to a chromate. (*See Foerster, Elektrochemie Wässeriger Lösungen, 1905.*)

ELECTROLYSIS OF SODIUM OR POTASSIUM CHLORIDE. — The electrolysis of sodium or potassium chloride may yield several different products, depending on the kind of cell employed. In the following discussion the reactions for sodium choride are given; these reactions also apply to potassium chloride when K is substituted for Na.

Production of Electrolytic Bleach. — If there is no diaphragm and the solution is kept cool, the chlorine and hydrate react on each other to form principally sodium hypochlorite or "electrolytic bleach," according to the equation

$$2\,NaOH + Cl_2 = NaOCl + NaCl + H_2O.$$

As soon as hypochlorite is formed, it begins to change to chlorate, but at first not as rapidly as it is formed. As the concentration of the hypochlorite increases, a larger and larger proportion changes to chlorate, until finally the concentration of the hypochlorite reaches a limit, which depends on the temperature, original salt concentration, current density, and other factors. The hypochlorite then changes to chlorate as rapidly as it is formed.

The reactions by which hypochlorite changes to chlorate are two; (1) the action of the discharged ClO ion on water:

$$6\,ClO + 3\,H_2O = 2\,HClO_3 + 4\,HCl + 1\tfrac{1}{2}\,O_2,$$

and (2) in a slightly acid solution:

$$2\,HOCl + NaOCl = NaClO_3 + 2\,HCl.$$

If the solution is warmed to about 50° C. the conditions are so changed that the limiting concentration of hypochlorite is much lower than when cold. Sodium and potassium hypochlorites are used only in solution, but the chlorates are crystallized out.

By further electrolysis of a cooled sodium (or potassium) chlorate solution, perchlorate, $NaClO_4$, is produced by the action of the liberated ClO_3 ion on water:

$$2\ ClO_3 + H_2O = HClO_4 + HClO_3$$

and

$$HClO_4 + NaOH = NaClO_4 + H_2O.$$

In most of the cells used for producing hypochlorite, a vessel is divided into a number of narrow compartments by bipolar or intermediate electrodes, consisting of carbon plates (Hass and Oettel) or platinum-iridium wire wound on glass plates (the Kellner cell). The solution is cooled by circulation. There is no essential difference between a hypochlorite and a chlorate cell, except that the latter is used at a higher temperature. (*See numerous volumes in the Engelhardt Monographs.*)

Production of Chlorine and Caustic. — If the anode and cathode are separated by a diaphragm of some kind, sodium hydrate is produced at the cathode by the action of the alkali metal on water:

$$2\ Na + 2\ H_2O = 2\ NaOH + H_2,$$

while at the anode chlorine is set free, which may be used to make bleaching powder.

Various devices are used to separate the hydrate and chlorine in cells intended for these products. In the McDonald cell (*Electrochem. Ind., Vol. 1, page 387, 1903*) and others a porous diaphragm is used. In the Hargreaves-Bird cell (*U. S. Pat. 655,343, 1900; 596,157, 1897*), the porous diaphragm is supported by a heavy copper gauge cathode, which is wetted only by the solution percolating through the diaphragm. In the Townsend cell (*Electrochem. and Met. Ind., Vol. 5, page 209, 1907*) the cathode compartment is filled with kerosene oil. During electrolysis the solution in the anode compartment percolates through the porous diaphragm and the perforated cathode, and on coming in contact with the oil forms drops and sinks to the bottom of the cathode compartment where it is collected. In the "bell process" the anode is inside an inverted nonconducting, nonporous bell, and the cathode is a conducting ring outside.

In the Castner cell the compartments are separated by a mercury diaphragm, acting as an intermediate electrode; and in the Solvay and the Whiting cells a mercury cathode is used, which, when charged with sodium in the electrolytic cell, is decomposed by water in a different compartment. The sodium amalgam reacts with water like metallic sodium. (*See the Engelhardt Monographs.*)

ELECTROLYSIS OF WATER. — The electrolysis of water is carried out on a commercial scale for the production of hydrogen and oxygen. The electrolyte is usually a 15-per-cent sodium hydrate solution. A diaphragm of canvas is used to separate the hydrogen and oxygen in the Flamand cell, now in use by the International Oxygen Company at Newark, N. J. The vessel containing the electrolyte is cast iron and acts as the cathode; the anode is steel. In the Siemens and Halske apparatus the gases are separated by a metallic gauze while bubbling to the surface of the solution; the Garuti and Pompeili apparatus is based on a similar principle. (*See Viktor Engelhardt, Die Elektrolyse des Wassers, 1902.*)

ELECTROTHERMAL PROCESSES. — Some of the more important industrial electrothermal processes and products and the various types of electric furnaces are described in the article on ***Furnaces, Electric.***

OZONE (O_3) is made by the silent discharge of electricity through dry air. The electrodes are water cooled, and protected to prevent the passage of sparks. From 8000 to 50,000 volts alternating are applied, this voltage being obtained from a small step-up transformer. For the Siemens and Halske ozonizer the concentration of the ozone is about 2 or 3 grams per cubic meter of the air which passes through it, and the yield is from 18 to 37 grams per kilowatt hour. (*Electrochem. Ind., Vol. 2, p. 67, 1904.*) The General Electric Company manufacture several types of small ozonizers, and are about to put the Siemens and Halske ozonizer on the market in this country.

BIBLIOGRAPHY. — In addition to the references given above, the following books should be consulted for further information regarding industrial electrochemical processes:

[M. DE K. THOMPSON.]

ELECTROCHEMISTRY, PRINCIPLES OF.—(*See also Electricity and Magnetism, Principles of; Elements, Chemical; Electrochemical Processes, Industrial; Furnaces, Electric.*) Electrochemistry is the science which deals with the phenomena resulting from the direct transformation of electrical into chemical energy or the converse transformation of chemical into electrical energy. By general usage the term, especially as applied to industrial processes, has come to include also those thermochemical phenomena which occur at temperatures produced in electric furnaces, although in such processes electrical energy frequently plays no other rôle than that of generating heat.

The following is a brief table of contents of this article:

DEFINITIONS. — The following terms are commonly used:

Element. — An element is a substance which cannot be decomposed into simpler substances by any known means of chemical analysis. (*See Table of Electrochemical Equivalents below, and article on Elements, Chemical.*)

Atoms and Atomic Weights. — An atom is the smallest mass of an element that can enter into chemical combination with another element or itself. The atomic weight of an element is a number which is proportional to the smallest known combining mass of the element, that of oxygen being chosen as the standard and taken as 16. The relative proportions, by mass, of the elements forming any substance are simple multiples of these numbers. For table of the atomic weights of the more common elements see below, and for a complete table see article on *Elements, Chemical.* On the atomic theory the atomic weight is proportional to the mass of the atom.

Molecules and Molecular Weight. — A molecule is the smallest mass of a substance which can exist and preserve its chemical properties. The molecular weight of an element or of a chemical compound is equal to the sum of the atomic weights of the atoms contained in the molecule, and may readily be calculated from the atomic weights when the molecular symbol of the compound is known. Thus the molecular weight of oxygen, O_2, is $2 \times 16.00 = 32.00$ as there are two atoms in the molecule. The molecular weight of silver nitrate, $AgNO_3$, is $107.88 + 14.01 + 3 \times 16.00 = 169.89$.

Radical. — A radical is a combination of two or more elements which persists as a group in chemical reactions, e.g., the SO_4 in H_2SO_4 is a radical, as exemplified by the reaction $H_2SO_4 + Zn = ZnSO_4 + H_2$.

Formula Weight. — The formula weight of an atom, radical or molecule is the sum of the atomic weights of the elements of which it is formed. For example, the formula weight of an oxygen atom, O, is 16; the formula weight

of an oxygen molecule, O_2, is 32; the formula weight of the radical NO_3 is 62.01.

Valency. — An adequate consideration of valency would involve a discussion beyond the limits of this article. As a simple definition, the valency of an acid or acid radical may be taken as the number of replaceable hydrogen atoms which the acid molecule contains, the valency of the hydrogen atom being always equal to unity. Thus hydrochloric acid, HCl, and nitric acid, $H(NO_3)$, are univalent acids and the elements H and Cl and the radical NO_3 are univalent; sulphuric acid, $H_2(SO_4)$, is a bivalent acid and SO_4 a bivalent radical; $H_3(PO_4)$ is a trivalent acid and PO_4 a trivalent radical, etc. Similarly, in a salt like sodium chloride, NaCl, sodium is a univalent metal, since one atom of sodium replaces one atom of hydrogen in the corresponding acid. But in barium chloride, $BaCl_2$, barium is a bivalent metal, as it replaces the hydrogen of two molecules of hydrochloric acid to form the salt. To completely describe the valency of a salt it is therefore necessary to stipulate the valency of the basic and acid constituents; thus sodium chloride, NaCl, is a uni-univalent salt; sodium sulphate, Na_2SO_4, is a uni-bivalent salt, the basic constituent being univalent and the acid constituent bivalent. Barium sulphate, $BaSO_4$, on the other hand, is a bi-bivalent salt. The valency of a number of elements varies according to the compound of which the element forms a part, e.g., copper is bivalent in cupric salts like $CuSO_4$ but univalent in cuprous salts as CuCl; iron is bivalent or trivalent according as it is a constituent of a ferrous or ferric salt respectively.

Bonds or Affinities. — An atom or radical is sometimes said to possess a number of "bonds" or "affinities" equal to its valency in the compound of which it forms a part.

Equivalent Weight — Chemical Equivalent. — The equivalent weight of an atom, ion or radical is defined as its formula weight divided by its valency. The equivalent weight of an element or compound is also referred to as its "chemical equivalent." The equivalent weight of an acid, base or salt is its molecular formula weight divided by the highest valency of either of its ions. As hydrogen exhibits no other valency than unity its equivalent weight and atomic weight are identical. Similarly, the equivalent weight and molecular weight of hydrochloric acid, HCl, are each 36.47. Copper in copper sulphate, $Cu(SO_4)$, and in cupric chloride, $CuCl_2$, has a valency of 2, hence equivalent weights of these salts are one half their molecular weights respectively.

In computations of electrochemical reactions it is frequently convenient to take as the unit of mass (or weight) of a substance, a mass in grams equal to the number expressing the atomic weight, ionic weight, molecular weight or equivalent weight of the substance. The following names have been given these units.

Gram-Atom or Gram-atomic Weight. — A number of grams of an element equal to its atomic weight, e.g., one gram-atom of oxygen is 16 grams.

Gram-Molecule or Mol. — A number of grams of a substance equal to its molecular weight, e.g., one mol of silver nitrate, $AgNO_3$, is 169.89 grams.

Gram-Equivalent. — A number of grams of an atom, radical or molecule equal to its equivalent weight, i.e., to its formula weight divided by its valency. For example, a gram-equivalent of sulphuric acid is $98.09/2 = 49.04$ grams. A gram-equivalent is usually represented by the chemical formula divided by the valency, e.g., a gram-equivalent of sulphuric acid is denoted by $\frac{1}{2} H_2SO_4$.

Electrolyte — Electrolysis. — When an electric current is passed through certain substances a chemical reaction takes place at the places where the current enters or leaves the substance. Such substances are called "electro-

lytes;" if the current effects a decomposition or chemical change in the electrolyte the process is called "electrolysis."

Electrodes — Anode and Cathode. — Electrodes are the conductors by which the current enters and leaves the electrolyte. The electrode at which the current enters the electrolyte is called the "anode," and that by which the current leaves the electrolyte is called the "cathode." The anode is therefore that electrode which is connected to the positive terminal of the generator; the cathode that connected to the negative terminal.

Ions — Anions and Cations. — The constituents of an electrolyte which are *primarily* liberated or deposited from an electrolyte at the electrodes are called "ions." The term also applies to the constituents of an electrolyte which conduct the current. (*See sections below on Dissociation Theory and Theory of Electrolytic Conduction.*) The ions liberated at the anode are called "anions," while those liberated at the cathode are called "cations." For example, when a current enters and leaves an aqueous solution of copper sulphate, $CuSO_4$, at platinum electrodes, the $CuSO_4$ is decomposed, the copper Cu being liberated from the solution and deposited on the cathode, and the SO_4 being liberated at the anode where it reacts with the water to form oxygen gas and sulphuric acid. The copper in the sulphate solution is therefore a cation and the SO_4 an anion. In general the metal atoms in salts and bases and the replaceable hydrogen atom in acids are cations, while the acid radicals (e.g., SO_4) and the basic radicals (e.g. OH in KOH) are anions.

The terms anion and cation are also used to designate specifically the negative and positive constituents of an electrolyte. For example, in dilute aqueous solution, a molecule of hydrochloric acid, HCl, is looked upon as consisting of one hydrogen cation and one chlorine anion; sulphuric acid, H_2SO_4, of two hydrogen cations and one SO_4 anion. There is much evidence to indicate that a negative charge of fixed amount is associated with each anion and a positive charge (or deficit of negative electricity) of equal amount is associated with each cation, irrespective of the chemical nature of the ion, except that the charges carried by any ion are directly proportional to its valency. The charge carried by every univalent ion is estimated as 5×10^{-10} electrostatic units, the charge carried by every bivalent ion is twice this amount, etc., 5×10^{-10} electrostatic units of negative electricity being the charge of an electron. Hence on the basis of the electron theory, a univalent anion as Cl has associated with it one free electron, a divalent anion as SO_4 two electrons, while a univalent cation as H has a deficit of one electron, a divalent cation as Cu has a deficit of two electrons, etc. See *Electron Theory*.

To distinguish cations and anions from neutral atoms or molecules, small plus or minus signs are often written over the symbol, the number of such signs being equal to the valance of the ion. Thus

$\overset{+}{H}$, $\overset{+}{Na}$, $\overset{++}{Cu}$, $\overset{+++}{Fe}$ (ferric iron) represent cations; $\overset{-}{Cl}$, $\overset{-}{NO_3}$, $\overset{--}{SO_4}$, $\overset{---}{PO_4}$ anions, etc.

Ionic Weight. — The formula weight of an ion is called its ionic weight.

Gram-Ion. — A number of grams of an ion equal to its ionic weight, e.g., one gram-ion of hydrogen is 1.008 grams, and one gram-ion of SO_4 is 96.07 grams.

Electrochemical Equivalent. — The electrochemical equivalent of an ion is the mass in grams of the ion liberated or deposited by one coulomb.

Electrochemical Constant or "Faraday." — The electrochemical constant, denoted by F, and called the "Faraday," is the number of coulombs required to liberate one gram-equivalent of any ion. It is a constant for all ions, and its value, as adopted by the International Congress of Applied Chemistry in 1911, is $F = 96,540$ coulombs.

Solvent, Solute and Solution. — When a substance A "dissolves" in another substance B, the substance A which dissolves is called the "solute," and the substance B is called the "solvent." The two substances together form a "solution."

Osmotic Pressure. — The osmotic pressure of a solution may be regarded as the force in virtue of which a solute tends to diffuse from regions of higher to regions of lower concentration. It can be measured by separating the solution and solvent by means of a diaphragm which is permeable to the solvent but not to the solute. (See section below on *Theory of Solutions*.)

Specific Conductance (κ). — The specific conductance of a solution is the reciprocal of its specific resistance, i.e., it is the conductance of a column of liquid one centimeter long and one square centimeter cross section. It is expressed in reciprocal ohms, or mhos, and is denoted by κ.

Concentration (c). — The concentration (c) of a solution is the quantity of the solute contained in unit volume of the solution. Thus it may be expressed as grams per cubic centimeter or grams per liter, etc.

Equivalent Concentration (η). — The equivalent concentration of a solution is the number of gram-equivalents of solute contained in one cubic centimeter of the solution; it is denoted by η. Calling w the equivalent weight of the solute, $\eta = c/w$.

Dilution (ϕ). — The dilution of a solution is the reciprocal of its concentration, i.e., it is the number of cubic centimeters of solution in which one gram-equivalent of solute is dissolved. It is denoted by ϕ. Hence, $\phi = 1/\eta$ and $\eta = 1/\phi$.

Normal Solution. — A normal solution is a solution containing one gram-equivalent of solute per liter. For such a solution $\eta = 10^{-3}$ or $\phi = 1000$.

Equivalent Conductance (Λ). — The equivalent conductance of a solution at the dilution ϕ is the conductance which a volume (in cu. cm.) of the solution containing one gram-equivalent of the solute would have, if placed between parallel plate electrodes one centimeter apart. It is denoted by Λ_ϕ or Λ_η, according as the dilution or concentration of the solution is given. Hence $\Lambda_\phi = \phi\kappa$, or $\Lambda_\eta = \kappa/\eta$.

The dilution or concentration of a solution should always be stated in connection with its equivalent conductance, otherwise the expression is indefinite.

Heat of Reaction. — The heat of reaction is the heat energy given out or absorbed in a chemical reaction. It is usually expressed in calories; see *Heat and Heat Effects*. Ostwald recommends the use of a calorie equal to 100 times the mean gram-calorie for expressing thermochemical data and this will be adopted in the present discussion. It will be denoted in this article by "cal."

Exothermic Reactions. — Reactions in which heat is given out to the surrounding bodies.

Endothermic Reactions. — Reactions in which heat is absorbed from the surrounding bodies.

NOTATION. — The notation used in this article is, in most instances, that proposed by the Bunsen Gesellschaft and adopted by the Fifth International Congress of Applied Chemistry in Berlin, 1903. For convenience of reference the symbols most frequently used are tabulated below.

κ = specific conductance in reciprocal ohms;

η = concentration, expressed as gram-equivalents of solute per cubic centimeter solution;

ϕ = dilution, expressed as cubic centimeters of solution per gram-equivalent solute;

Λ = equivalent conductance;
Λ_∞ = equivalent conductance at infinite dilution;
γ = degree of ionization;
E = electrical potential difference;
I = current strength;
R = resistance [W adopted by International Congress]
e = single potential difference, taken positive in direction of rise of potential;*
e_h = potential difference measured against a normal hydrogen electrode;
e_c = potential difference measured against a normal calomel electrode;
R = gas constant per mol
F = the Faraday = 96,540 coulombs per gram-equivalent
T = absolute temperature in degrees centigrade.
t = centigrade temperature [Θ adopted by International Congress]

CHEMICAL EQUATIONS. — A chemical equation, such, for example, as that representing the solution of zinc in a dilute hydrochloric acid solution (Aq = water),

$$Zn + 2\,HClAq = ZnCl_2Aq + H_2,$$

is to be interpreted as follows: one gram-atom (65.37 grams) of zinc reacting with 2 mols (2 × 36.47 = 72.94 grams) of hydrochloric acid in aqueous solution forms one mol (65.37 + 2 × 35.46 = 136.3 grams) of zinc chloride in solution and one mol (2 × 1.008 = 2.016 grams) of hydrogen gas. Since atomic weights are relative numbers, any unit of weight, as the pound or kilogram, may be substituted for gram in this statement.

If the reaction is intended to express not only the chemical change which takes place, but also the energy change involved, the "heat of the reaction" must be included, thus:

$$Zn + 2\,HClAq = ZnCl_2Aq + H_2 + 342 \text{ cal.}$$

This thermochemical or energy equation signifies that the intrinsic energy represented by the initial system, consisting of 65.37 grams of zinc and 72.94 grams of hydrochloric acid dissolved in enough water to form a dilute solution, is 342 calories (1 gram of water from 0° to 100° C.) greater than that represented by the final system, consisting of 136.3 grams of zinc chloride dissolved in water and 2.016 grams of hydrogen gas; in other words when the substances in the initial system react and form the substances in the final system, an amount of heat energy is evolved equal to 342 cals. When energy is given up by a system to the surroundings (exothermic reactions), as in the above illustration, it is regarded as positive. If a reaction is accompanied by an absorption of heat energy (endothermic reactions), i.e., if the system takes up heat and thereby tends to cool the surroundings, the sign of the heat of the reaction is taken as negative.

FARADAY'S LAWS. — The first quantitative relations between the magnitude of an electric current and its chemical effect were discovered by Faraday in 1834 and are known as Faraday's Laws. They may be stated as follows:

First Law. — The quantity of an electrolyte decomposed by an electric current is directly proportional to the total quantity of electricity which passes through the electrolytic cell; or, the rate of chemical decomposition is directly proportional to the current. The amount of decomposition is independent of the voltage and intensity of the current, size of electrodes and concentration of electrolyte, so long as the total *quantity* of electricity flowing through the

* This notation is employed to harmonize the notation in this article with that used elsewhere in this book. The Berlin Congress recommends the use of the symbol ϵ for a potential difference taken positive in the direction of the *drop* of potential.

circuit remains constant. (These factors, however, do affect the *ultimate products* of an electrolysis.

Second Law.—A given quantity of electricity always decomposes equivalent weights of different electrolytes irrespective of their nature. For example, if three electrolytic cells containing aqueous solutions of silver nitrate $AgNO_3$, copper sulphate $CuSO_4$, and cuprous chloride CuCl (dissolved in sodium chloride), respectively, be connected in series and the same quantity of electricity passed through each, it will be found if *a* grams of silver are deposited in the first cell, *b* grams of copper in the second and *c* grams of copper in the third, that the following proportion holds between these weights: $a : b : c = \frac{107.88}{1} : \frac{63.57}{2} : \frac{63.57}{1}$, where 107.88 and 63.57 are the atomic weights of silver and copper respectively. In copper sulphate the valency of copper is 2, while in cuprous chloride its valency is 1; silver is always univalent and hence the weights *a, b, c* are proportional not to the atomic weights but to the *equivalent weights* of the metals in the compounds from which they are electrolyzed. It follows from this that a given current will deposit in a given time twice the weight of metal from a salt in which it is combined with a valency of 1, as from a salt in which it exists with a valency of 2. Thus, the same current deposits in a given time twice the weight of copper from a cuprous as from a cupric salt solution. In general, if the ion in a compound has a valency *n*, the quantity of electricity required to liberate it will be *n* times as great as that required to liberate the same ion from a compound in which it is univalent.

It is to be noted, since the numbers expressing the atomic weights of the elements, and hence their equivalent weights, are purely relative, that the relative weights of substances decomposed by a given quantity of electricity may be expressed in grams, kilograms, pounds or any other unit of weight. Thus, in the above illustration the quantity of electricity which will deposit $\frac{63.57}{2} = 31.79$ pounds of copper from a copper sulphate solution will deposit 107.88 pounds of silver.

Faraday's Laws are the expression of the results of direct experiment and have been tested to the limit of precision with which physical and chemical measurements are capable of being carried out at the present time. All evidence indicates that they hold rigidly, i.e., that they are exact laws of nature. In cases where exceptions have seemed to exist these have been shown to arise from secondary causes.

Value of the Electrochemical Constant or Faraday. — The determination of the number of coulombs required to deposit one gram-equivalent of an ion, i.e., the constant connecting the quantity of electricity and the mass of a substance liberated, involves two distinct investigations; first, the measurement of the number of coulombs which pass through a given electrolytic cell, and second, the determination of the amount of the chemical decomposition. The importance of the constant has enlisted the skill of a number of the ablest physicists, and its value is still being investigated at the present time.

The various methods which have been employed vary primarily in the means adopted for measuring the current. A primary instrument, the constants of which can be computed from its dimensions, is essential. Tangent galvanometers and various forms of current balances or dynamometers have been constructed for this purpose. The ultimate precision of the measurements with these instruments is thus referred back to instrumental constants and to the accuracy with which the horizontal component of the earth's field, or the value of the acceleration due to gravity, is known at the place where the research is carried out, respectively.

The amount of silver deposited from a silver nitrate solution has been adopted almost universally for the chemical part of the research. Owing, however, to the fact, established by T. W. Richards, that the amount of silver deposited depends to a slight extent upon whether or not the solution at the anode is allowed to diffuse to the cathode, the values obtained in some of the best earlier determinations are somewhat uncertain. To show the degree of precision with which the constant is now known the following résumé of the determinations of the mass of silver in milligrams deposited by one coulomb is given (*Guthe, Bulletin of the Bureau of Standards, 1905, Vol. 1, p. 363*).

TABLE I.—ELECTROCHEMICAL EQUIVALENT OF SILVER IN MILLIGRAMS PER COULOMB

Observer	Year	Found	Electrochemical equivalent corrected by		
			Richards and Heimrod	Van Dijk	Guthe
		mg.	mg.	mg.	mg.
Mascart	1884	1.1156	......	1.1155	1.1153
Fr. and W. Kohlrausch	1884	1.1183	1.1173	1.1182	1.1177
Rayleigh and Sidgwick	1884	1.1179	1.1175	1.1178	1.1176
Gray	1886	1.1183	......	......	1.1178
Koepsel	1887	1.1174	......	......	1.1169
Pellat and Potier	1890	1.1192	......	1.1191	1.1189
Patterson and Guthe	1898	1.1192	1.1175	1.1180	1.1177
Pellat and Leduc	1903	1.1195	......	1.1192	1.1190
Van Dijk and Kunst	1904	1.1182	......	1.1180	1.1178
					Mean 1.1176

If the atomic weight of silver be taken as 107.88 (latest corrected value) the value of the Faraday from the average of Guthe's corrected values is $F = \frac{107.88}{0.0011176} = 96{,}530$ coulombs. This value agrees very closely with the value $F = 96{,}540$ adopted by the International Congress of Applied Chemistry in 1903 and based on the atomic weight of silver = 107.93, and on the definition of the legal ampere as that current which in one second deposits 0.001118 gram of silver. (*See Report of International Electrical Congress, 1893; Definition legalized by the U. S. Government in 1894.*) In view of the above agreement it seems advisable to adhere to the value 96,540 until by international agreement another value shall be adopted.

ELECTROCHEMICAL EQUIVALENTS OF THE ELEMENTS.—From the definitions of the electrochemical equivalent and the Faraday, it follows that the electrochemical equivalent of any ion, expressed in grams per coulomb (one ampere per second) is equal to

$$\frac{\text{gram-equivalent of the ion}}{96{,}540}.$$

Table II contains the values of the electrochemical equivalents of the more common elements which may be found useful in certain calculations. The

electrochemical equivalent of any radical may be readily calculated from its formula; for example, the electrochemical equivalent of SO_4 is

$$(32.07 + 4 \times 16)/2 \times 96{,}540 = 0.0004975 \text{ gram or } 0.4975 \text{ milligram.}$$

TABLE II.—ELECTROCHEMICAL EQUIVALENTS OF THE MORE IMPORTANT ELEMENTS

(Based on atomic weights of 1913, and $F = 96{,}540$ coulombs)

Element	Symbol	Atomic weight	Valence	Milligrams deposited by one ampere in one second	Grams deposited by one ampere in one hour
Aluminum	Al	27.1	3	0.0935	0.3366
Antimony	Sb	120.2	3	0.4152	1.495

CONDUCTIVITY OF ELECTROLYTES—Solutions. — (*See also article on Resistance and Conductance.*) The specific conductance of an electrolytic solution varies between wide limits. It depends upon the nature of the solute and of the solvent, on the temperature and on the concentration of the solution. The effect of these factors is discussed below. For numerical values see Kohlrausch & Holborn, *Leitvermögen der Electrolyte;* Landolt-Börnstein, *Tabellen.*

Fused Electrolytes. — Most inorganic salts conduct electrolytically when heated to a sufficiently high temperature to cause them to pass into the liquid state. For such electrolytes Faraday's, Ohm's, and Joule's Laws hold as they do in the case of solutions. The conductance increases in general from 1 to 1½ per cent per degree centigrade. An exhaustive résumé of all matters relating to fused electrolytes may be found in Lorenz's *Electrolyze der Geschmolzene Salze.* On account of their enormous concentration (100 per cent) the specific conductance of fused salts is generally very high. This, together with the difficulty of obtaining a non-conducting chemically inert vessel of suitable shape to contain the salt and the difficulty of regulating high temperatures to a fraction of a degree, makes the measurement of the conductivity of fused electrolytes far more difficult than in the case of solutions. Fused silica and natural quartz crystals have been successfully used for conductivity cells. For recent work see Goodwin and Mailey, *Physical Review*, Vol. 25, p. 469, 1907; Vol. 26, p. 28, 1908; Goodwin and Kalmus, *Physical Review*, Vol. 28, p. 1, 1909; Arndt, *Zeit. für Electrochem.*, Vol. 12, p. 337, 1906; Vol. 13, p. 509, 1907; Vol. 14, p. 662, 1908; Foot and Martin, *Am. Chem. J.* 41, 451, 1909; Landolt-Börnstein *Tabellen.*

VOLTAIC AND ELECTROLYTIC CELLS. — When a cell formed by two electrodes and one or more electrolytes gives out electric energy the cell is called a "voltaic" cell. All ordinary chemical batteries are voltaic cells. If across the terminals of a cell an external electromotive force, greater than the electromotive force developed within the cell, is impressed, then a current will flow through the cell in the opposite direction, and the cell will absorb electric energy. A cell which absorbs electric energy is usually referred to as an

"electrolytic cell." The cells used in electrolytic refining and similar processes are electrolytic cells. An electrolytic cell may or may not have an electromotive force on open circuit, but may develop an electromotive force in virtue of the chemical changes or changes in concentration which take place due to the current forced through it by some external source. A voltaic cell, of course, becomes an electrolytic cell when the electromotive force impressed across its terminals exceeds (and opposes) its own electromotive force.

POLARIZATION. — When an electric current passes through either a voltaic or an electrolytic cell there is, in general, developed at the electrodes of the cell, as a result of the chemical actions and changes in concentration which take place, a *back* or *counter-electromotive* force, in addition to its open-circuit electromotive force (if any); and an *increase in the resistance* of the cell, in addition to the change in resistance due to the heating effect of the current. Both of these effects cause a decrease in the strength of the current through the cell. These two phenomena are said to be due to "polarization" and "transition resistance" respectively.

Even in the case where the electrolyte, as a whole, suffers no change in concentration, as in the electrolysis of copper sulphate between copper electrodes, a counter e.m.f. of polarization is produced in consequence of the difference in concentration of the copper ions in the neighborhood of the anode and cathode. Vigorous stirring of the electrolyte tends to reduce this concentration difference and the resulting polarization, but, except for very low current densities, it cannot be completely eliminated. It is for this reason, in refining processes, that energy is required to transfer the metal from anode to cathode in addition to that necessary to overcome the internal resistance of the cell.

A transition resistance results from the formation of a film of poorly conducting material over the electrode and may or may not be present according to the character of the electrolysis.

Measurement of E.M.F. of Polarization and Transition Resistance. — As both transition resistance and polarization tend to cut down the current flowing through the cell, they cannot be distinguished by this effect alone. The transition resistance may be determined by measuring the ohmic resistance of the cell before and after the passage of the current by the usual alternating-current method. The existence of an e.m.f. of polarization in a cell which normally has no open-circuit e.m.f. may be qualitatively demonstrated by short-circuiting the cell through a galvanometer immediately after breaking the primary circuit; if the cell be polarized, a current which diminishes to zero will flow through it in the reverse direction. A voltmeter, or, better, an electrometer connected across the electrolytic cell, will indicate the polarization voltage the instant after the current is broken. This voltage will diminish as the polarization disappears, the rate depending upon the current through the voltmeter and the rate of diffusion of the electrolytic products causing the polarization. Owing to the rapidity with which the e.m.f. of polarization falls off after the exciting cause is removed, special precautions must be observed in its measurement. One of the best methods is to connect up the circuit containing the applied e.m.f., and electrolytic cell with a tuning-fork interrupter and electrometer so that at the instant the battery current is broken at each vibration of the fork, the circuit containing the cell and electrometer or voltmeter is closed, and vice versa. By this arrangement, the e.m.f. of polarization is measured during the fraction of a second that the battery circuit is open, and before it has had time to sensibly diminish. The polarizing current may also be regarded as practically constant.

It is frequently of importance to know, not the polarization of the cell as a whole, but the polarization at each electrode. This is obtained by measuring

the drop in potential at each electrode against a normal hydrogen or calomel electrode while the impressed e.m.f. is acting on the electrolytic cell, or immediately after the current through the cell is interrupted.

REVERSIBLE ELECTRODES — DEPOLARIZERS. — If the chemical and thermal actions which take place at a given electrode when a given quantity of electricity passes in one direction through a cell are exactly the reverse of the actions which take place when the same quantity of electricity passes through it in the opposite direction, the electrode and the solution with which it is in contact are said to form a "reversible electrode." Such an electrode does not polarize provided the concentration of the solution is kept constant. There are two types of reversible metal-liquid electrodes, namely:

Electrodes of the First Type, consisting of a metal in contact with a solution of one of its own salts, e.g., copper in copper sulphate, zinc in zinc sulphate, etc. The two electrodes of a Daniell cell are of this type.

Electrodes of the Second Type, consisting of a metal in contact with a solution containing one of its difficultly soluble salts and a second soluble salt having the same anion of some other metal; the difficultly soluble salt, called the "depolarizer," must be present in excess as solid. Such an electrode is mercury in contact with a solution of zinc sulphate containing mercurous sulphate in excess as solid; this is one of the electrodes of the Clark cell. (*See article on Cells, Standard.*)

Reversible Gas Electrode. — An electrode consisting of "platinum black" saturated with an atmosphere of hydrogen gas and dipping partially into a solution containing hydrogen ions is also a reversible electrode. This is a special form of electrode of the first type in which a gas by being occluded in platinum is made to play the rôle of a metal.

CONTACT POTENTIALS OR ELECTROMOTIVE FORCES. — The electromotive force of any voltaic cell, the back-electromotive force of any electrolytic cell, and the electromotive force of a thermocouple, are all due to differences of potential which always exist at the junction of dissimilar substances. These potential differences are called contact electromotive forces or "contact potentials," the word "difference" in the latter case being understood.

Metal-metal Potentials. — The potential at the junction of two dissimilar metals may be measured either by the Peltier effect, i.e., by the heat developed or absorbed at the junction when a known quantity of electricity is forced across it, or by the thermoelectric force set up in a circuit formed by the two metals in question when the two junctions are kept at different temperatures. In the former case the potential may be calculated from the expression $e = H/nF$ when H is the Peltier heat developed or absorbed at the junction by the passage of nF coulombs. In the latter case $e = T\frac{de}{dT}$, where $\frac{de}{dT}$ is the thermoelectric coefficient of the junction at the absolute temperature T. Both methods give results which prove that the potential difference thus arising is of the order of magnitude of a few millivolts, except in the unusual combination of antimony and bismuth where it amounts to about 0.03 volt. Table III taken from a recent article by Caswell, *Physical Review*, 33, 401, 1911, contains the values of the metal-metal potentials for the more common metals against copper at ordinary temperature. The columns headed A give the values as determined by the first method, columns headed B give the values as determined by the second method. The plus sign (+) indicates that at a junction formed by the given metal and copper the given metal is at the higher potential, the minus sign (−) that it is at a lower potential than the copper.

TABLE III. — CONTACT POTENTIALS BETWEEN COPPER AND OTHER METALS, IN MILLIVOLTS

The contact potential difference between any two of these metals is the *algebraic* difference between the potentials of the two metals against copper; e.g., the contact potential difference between iron and platinum according to Jahn's measurements (*A*) is $+ 0.37 - (- 3.68) = 4.05$ millivolts.

The contact potential difference between any two metals is a function of the temperature, the sign of the potential for a given pair of metals sometimes reversing as the temperature rises. Although of importance in thermopiles, pyrometry and radiometry, metal-metal potentials are of little significance in considerations of the voltaic cell.

Metal-gas Potentials. — The contact potential differences between two metals should be carefully distinguished from potential differences having their origin in the so-called "Volta effect," i.e., potential differences which are manifested when two dissimilar metals in metallic contact are separated by an air or other gaseous gap. The two phenomena are quite distinct, there being no known relation between them.

Values of the potential difference across the air gap between combinations of some of the more common metals are given in the accompanying table. There is a fall of potential from the zinc to the lead through the air. This table is taken from data by Ayrton and Perry, *Phil. Trans.*, *Vol. 171, 1880.*

	Volts
Zinc — air — lead	0.210
Lead — air — tin...........	0.069
Tin — air — iron...........	0.313
Iron — air — copper...........	0.146
Copper — air — platinum......	0.238
Platinum — air — carbon......	0.113

Liquid-liquid Potentials.—When two dissimilar electrolytic solutions are brought into contact the phenom-

enon of diffusion takes place between them until a homogeneous mixture results. At the same time a difference of potential is produced between the solutions, the magnitude of which depends upon the velocity of migration and the relative concentration of the ions taking part in the diffusion, the charge which they carry, the absolute temperature and the gas constant. Liquid junction potentials like metal-metal potentials are, in general, of small magnitude. Thus the potential difference between two solutions of potassium chloride, one solution having 10 times the concentration of the other, is only 0.0004 volt, and diminishes as the ratio of the concentrations approaches unity, being, in fact, proportional to the logarithm of this ratio. Potassium chloride is often used as an intermediate electrolyte when it is desired to reduce the liquid-liquid potentials of a voltaic combination to a minimum because of the small potential to which it gives rise. For further details of eliminating liquid-liquid contact potentials, see Ostwald-Luther's *Physico-Chemische Messungen*, pages 448-449.

Liquid potentials are greatest between acid or between alkali solutions. Thus, between two hydrochloric acid solutions whose concentrations are in the ratio 10 to 1 at a temperature of 18° C., there is a potential difference of about 0.038 volt; between two sodium-hydrate solutions under the same conditions there is a potential difference of 0.034 volt, these voltages also varying as the logarithm of the concentration ratio. For formulas, see page 471.

Metal-liquid Potentials. — From what has been said regarding the magnitude of metal-metal and liquid-liquid potentials, it follows by the process of elimination that the main seat of the electromotive force of a voltaic cell must reside at the junctions between metals and liquids. The *absolute* value of the potential difference between a metal and the solution with which it is in contact can be found only on certain assumptions regarding the nature of surface tension; this point is again referred to below. For practical purposes the value of this potential is expressed as the e.m.f. of a cell constructed with two half elements, one of which is the given metal and solution, and the other some form of "normal" or reference electrode. Two normal electrodes are in common use, namely, the calomel electrode and the hydrogen electrode.

Normal Calomel Electrode. — The normal calomel electrode consists of mercury in contact with a normal solution of potassium chloride saturated with mercurous chloride, the latter being present in excess as a solid.

Normal Hydrogen Electrode. — The normal hydrogen electrode consists of a strip of platinum coated with a thin deposit of platinum black and saturated with hydrogen gas at atmospheric pressure. The electrode is mounted partially surrounded by hydrogen gas and partially dipping into an acid solution of such a concentration that it contains 1 gram-equivalent of hydrogen ion per liter. A sulphuric-acid solution containing 2 gram-equivalents per liter sufficiently fulfills this condition. Hydrogen gas is allowed to bubble through the solution continuously.

Following the recommendation of the International Congress of Applied Chemistry in 1903, all metal-liquid potentials should hereafter be given as directly measured against either the normal calomel or the hydrogen electrode, uncorrected for liquid junction potentials.

From a normal hydrogen electrode to a normal calomel electrode there is a rise of potential through the electrolyte of 0.283 volt, hence, if from a hydrogen electrode to any metal electrode the rise of potential is e_h, and if from a calomel electrode to any metal electrode the rise of potential is e_c, then

$$e_h = e_c + 0.283 \text{ volt.}$$

The difference between any two metal-liquid potentials remains the same irrespective of the normal electrode to which they are referred.

Electrode Potentials of the Common Elements. — Table IV contains the most reliable values known at present of the metal-liquid potentials of the more common elements when in contact with solutions containing one gram-ion of the element per liter. When the concentration of the solution is thus determined the value of the metal-liquid potential is called the "electrode potential" of the metal. This term is however frequently used in the general sense of potential at the junction of a metal and solution irrespective of its concentration. When not otherwise stated the values in the table hold for room temperatures. e_c is the value (measured or computed) against the calomel electrode; e_h the value (measured or computed) against the hydrogen electrode. (*See LeBlanc, Electrochemie, ed. 1911, page 240.*) Values in parentheses are computed from heats of reaction (*see below*). The + sign indicates that the given metal is at a higher potential than the standard electrode, the − sign that it is at a lower potential.

TABLE IV. — ELECTRODE POTENTIALS IN VOLTS

(LeBlanc's Compilation, 1911. See text for the conditions under which these values hold.)

Element	e_c	e_h	Element	e_c	e_h

Pb	−0.402	−0.119			

Variation of Electrode Potentials with Concentration. — According to Nernst's theory of electrode potentials (*see below*) the *change* in the value of these potentials with concentration may be calculated by the following formula

$$e_1 - e_2 = \frac{0.000198\,T}{n} \log_{10} \frac{c_1}{c_2},$$

where e_1 is the potential at concentration c_1, and e_2 the potential at concentration c_2, T is the absolute temperature, and n the valence of the metal in the solution.

This formula is also justified by experiment. For example, the electrode potential of silver in a normal silver-nitrate solution at 25° C. is 0.798, referred to the normal hydrogen electrode. If the concentration of the silver ions be reduced to 1/1,000,000 its value in a normal solution, the electrode potential of silver will become

$$e_2 = 0.798 - \frac{0.000198 \times 298}{1} \log_{10} \left(\frac{1}{10^{-6}} \right)$$
$$= 0.798 - 0.0590 \times 6 = 0.444 \text{ volt.}$$

Electrochemical Series — Nobility of the Elements. — The elements, as arranged in Table IV, constitute the "Electrochemical Series." Those elements for which e_h is negative are said to be less "noble" than hydrogen, while those for which e_h is positive are said to be more "noble" than hydrogen. The alkali metals having the greatest tendency to form ions in water stand at one end, while the "noble" metals, such as gold, platinum, paladium, having but a very slight tendency to form ions, are at the other end. The halogens and oxygen which go into solution as negative instead of positive ions stand below the metals at the extreme lower end of the series. Other series have been given which differ from the above in that the elements are not compared under similar conditions in regard to the concentration of the solution with which they are in contact. Changing the electrolyte, e.g., to potassium cyanide alters not only the numerical values of the potentials, but may completely change the order in which certain elements occur in the series.

Any metal if placed in a solution of a salt of a metal standing below it in the series will tend to replace it; thus, zinc precipitates iron, copper, silver, etc., from their solutions but will not displace the alkali metals from solutions of their salts. Any metal standing above hydrogen will tend to displace it from an acid solution with evolution of hydrogen. Metals below hydrogen in the series will not dissolve in acid by a simple replacement of hydrogen. From a chemical standpoint the adoption of the hydrogen electrode as a standard has the advantage over the calomel standard that it divides the metals into two groups according to their behavior towards acids.

The approximate electromotive force of a battery consisting of two metals dipping into normal solutions of their respective salts may also be computed at once from the table by taking the difference of the two corresponding electrode potentials. Thus a zinc-copper cell should have an electromotive force equal approximately to $E_{zn-cu} = (e_h)_{zn} - (e_h)_{cu} = -0.770 - 0.329 = -1.099$, the rise of potential being from the zinc to the copper in the cell. As a matter of fact, this combination, the Daniell cell, has an electromotive force of approximately 1.10 volts. Other conclusions to be drawn from the table will be pointed out below.

ELECTROMOTIVE FORCE AND HEAT OF REACTION. — The electromotive force of a reversible cell maintained at constant temperature may be readily calculated from the first and second law of thermodynamics (*see Thermodynamics*). By a "reversible" cell is meant a cell which does not polarize and which operates under conditions such that changes which take place within the cell constitute a thermodynamically reversible process. (*See Thermodynamics, Principles of.*) The discussion given below also applies to a rough degree of approximation to most commercial cells, which, as a rule, are not strictly reversible.

Gibbs-Helmholtz Equation. — In the case of a reversible cell, such, for example, as the Daniell cell,* shown in Fig. 1, the relation between the heat of reaction (H) and the electromotive force (E) of the cell is calculated as follows.

From Faraday's Laws, the quantity of electricity which must flow through the cell in order to deposit or liberate one gram-ion at either electrode is nF coulombs, where n is the valency of the ion of highest valency involved in the chemical reaction and F is the electrochemical constant (*see above*). Hence, the external work done by the cell (when there is no other external work than electrical work) is nFE joules, where E is the e.m.f. of the cell. If the cell is kept at the same temperature (T degrees, absolute scale) as the surrounding bodies, then the external work nFE done by the cell is the maximum external work it can do at this temperature T (*see Thermodynamics, Principles of*). Hence, from equation (8) of the article on thermodynamics,

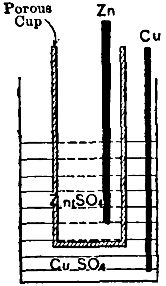

Fig. 1.

$$nFE = H' + nFT\frac{dE}{dT},$$

or

$$E = \frac{H'}{nF} + T\frac{dE}{dT},$$

where H' = the heat of reaction, in joules per gram-ion, corresponding to the chemical change which takes place.* H' gives the change in intrinsic energy corresponding to the chemical changes which take place within the cell. This can be found by an independent calorimetric measurement, by causing the reaction to take place under such conditions (*constant volume*) that heat is the only form of energy produced.

Temperature Coefficient of Electromotive Force. — From the above equation it follows that the energy developed by the cell is equal to the heat energy of the chemical reaction taking place within it plus a certain other quantity of energy equal to $nFT\,dE/dT$. This may be either positive or negative, according as the temperature coefficient of electromotive force dE/dT is plus or minus, i.e., according as the electromotive force of the cell increases or decreases with the temperature. If the electromotive force on open circuit increases with the temperature of the cell, then on closed circuit the cell will tend to cool, i.e., its temperature will fall, and its electromotive force will likewise decrease, the energy $nFT\,dE/dT$ being derived from the heat energy within the cell (or surroundings). If the electromotive force on open circuit decreases with increasing temperature of the cell, then on closed circuit the cell will tend to heat up, i.e., its temperature will rise and its electromotive force will decrease. A cell for which dE/dT is other than zero can work at constant temperature only by absorbing heat from or giving out heat to some surrounding body.

Only for the unique conditions that $dE/dT = 0$, or that $T = 0$, i.e., when the electromotive force is independent of the temperature or the cell works at temperatures approaching absolute zero, is $E = H'/nF$. By a curious chance it happens that the first of these conditions practically obtains in the case of the Daniell cell considered above. The electromotive force of the cell is nearly independent of the temperature. Its observed value is $E = 1.10$ volts, while its value computed by the above equation, putting $dE/dT = 0$, is 1.09 volts.

Thomson's Rule. — In computing the electromotive force of a battery from heats of reaction it is usually necessary to content oneself with a first

* Since 1 large mean calorie = 418.6 joules and $F = 96{,}540$, this may be written, putting H = heat of reaction in large mean calories,

$$E = \frac{H}{230.5\,n} + T\frac{dE}{dT}.$$

approximation and neglect the second term in the above equation, since at present few data are available from which the value of dE/dT can, a priori, be obtained. The approximate equation

$$E = \frac{H'}{nF} = \frac{H}{230.5\, n}$$

is known as Thomson's rule. (H' is in joules, H in large mean calories.)

This rule also applies approximately to most commercial cells, although these are not strictly reversible. Of course, the heat of reaction used must be that corresponding to the actual chemical changes which take place in the cell.

Nernst's Thermodynamic Theorem. — Nernst, by assuming that the values of the intrinsic energy and free energy of a system not only become equal at the absolute zero but also that they approach equality asymptotically at this point, has been able to express the electromotive force (E) of a cell explicitly in terms of the thermal properties of the substances taking place in the reaction. So far as the new formula has been tested a satisfactory agreement has been found between theory and experiment. The principles involved are of fundamental importance and are fully discussed in Nernst's *Silliman Lectures, Applications of Thermodynamics to Chemistry*. See also Nernst's *Theoretical Chemistry*, 6th ed., 1911, pages 709, 745.

Concentration Cells. — All commercial primary cells (*see Batteries, Primary*) are chemical cells, i.e., they derive the major part of their energy from the chemical reactions occurring within them. There is also a class of cells in which the electrical energy developed by the cells at constant temperature is derived from the heat energy of the surroundings, i.e., cells in which $H = 0$, and, therefore,

$$E = T\frac{dE}{dT}.$$

Integration of this equation shows that for such cells the electromotive force is proportional to the absolute temperature. Such cells are very simple of construction and are called concentration cells. They are of considerable importance from a theoretical point of view, and their electromotive force can be readily and exactly computed by an application of Nernst's formula for electrode potentials (*see above*). A pure concentration cell can be formed of any chemical or physical system in which the various parts tend to diffuse into each other without the evolution or absorption of heat, by constructing a cell in which the equalization of concentration, be it gaseous or liquid, is effected electrically. Numerous cases are discussed in Le Blanc's *Electrochemistry*, English translation, page 184, 1907 ed. If the two solutions forming a concentration cell when mixed have an appreciable "heat of dilution" the general Gibbs-Helmholtz formula and not the above special case is applicable.

Carbon Generator. — The problem of converting the energy liberated in the combustion of carbon to carbon dioxide directly into electric energy has not yet been practically solved. The reaction, $C + O_2 = CO_2$, liberates a very large quantity of heat, namely, 961 large calories per gram-atom of carbon consumed. Of this, only about 10 per cent is converted into electrical energy through the agency of a steam engine and dynamo. The difficulties encountered in devising a commercial carbon generator are the following: (1) the velocity of the above reaction is small, except at high temperatures; (2) it is difficult to utilize a gas as an electrode, except through the agency of a conducting medium which occludes it, such as platinum black; (3) a satisfactory high-temperature electrolyte which will not deteriorate in the presence of CO_2, is difficult to obtain; and (4) the slight tendency of carbon to form ions.

ELECTROLYTIC DECOMPOSITION. — Faraday's laws enable one to determine the amount of the substances primarily liberated or deposited at the electrodes of any electrolytic cell, but they do not enable one to predict the nature of the secondary chemical actions which may take place. (*See section on Secondary Reactions.*) The factors which determine what products will be formed in any given case are numerous. The chemical process occurring at the cathode is always of the nature of a reduction; at the anode, of an oxidation, these terms being used in their most general sense. It may be that the electrolyte, taken as a whole, undergoes no change, as is the case, for example, of a copper-sulphate solution when electrolyzed between copper electrodes. Here the chemical reaction at the cathode is the exact reverse of that at the anode. Generally, however, this is not the case; different chemical products are usually formed at the two electrodes, and appear either in the form of gas or as a solid precipitate, or remain dissolved in the electrolyte.

Decomposition Voltage of Electrolytes. — When a gradually increasing difference of potential is applied to the electrodes of an electrolytic cell, electrolysis does not in general begin at once but only after a certain minimum electromotive force is reached, even though the cell has no open-circuit e.m.f. It should be noted that this condition does not apply to the case when the electrodes are such that the electrolyte as a whole undergoes no change as a result of electrolysis. Thus, in the electrolysis of a zinc-sulphate solution between zinc electrodes an exceedingly small electromotive force is sufficient to maintain a steady current through it indefinitely (assuming that concentration changes at the electrodes are completely eliminated by stirring). Although, in this case, electrolysis starts at once, the electrolyte as a whole is not decomposed, for as much zinc dissolves at the anode as is deposited at the cathode. If a platinum anode be substituted for the zinc anode so that as a result of electrolysis zinc is separated at the cathode and oxygen gas is liberated at the anode, an e.m.f. of 2.35 volts is required to start the electrolysis. Again, if the electrolyte is an aqueous solution of sulphuric acid it requires a minimum voltage of 1.67 volts to liberate oxygen and hydrogen gas against smooth platinum electrodes. The minimum voltage necessary to decompose a compound electrolytically is called its "decomposition voltage." It is influenced by a variety of factors and conditions which will now be considered.

Measurement of Decomposition Voltage. — Decomposition voltages have been experimentally determined in several ways. Certain investigators have taken the value necessary to produce visible electrolysis as the criterion; others have followed the polarization at the electrodes until it became constant and assumed this value as that at which electrolysis begins. Results obtained by the so-called ammeter-voltmeter method must be accepted with caution. In this method the value of the electromotive force applied to the cell is gradually increased from zero and plotted as abscissas and the corresponding currents through the cell plotted as ordinates. The resulting curves have the general form shown in Fig. 2.

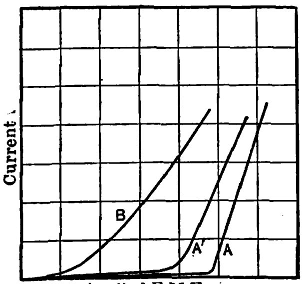

Fig. 2.

The slope of these current-voltage curves depends upon the internal resistance of the cell, the size and the distance apart of electrodes. The critical voltage at which the current suddenly increases in value is, however, quite sharply

defined with some electrolytes, e.g., silver nitrate between platinum electrodes, and other salts from which a metal is deposited. Below the critical voltage very little or no current passes through the cell and no visible decomposition at the electrodes is apparent. When the point *A* is reached, visible electrolysis begins. The sharpness of the bend in the curve and its course below *A* depend in large measure upon the sensitiveness of the galvanometer used for detecting the current, the size of electrodes and the tendency of the products of the electrolysis to go back into solution.

Residual Currents. — With a sensitive reflecting galvanometer, a steady deflection may be observed for days without any apparent electrolysis when an e.m.f. of a few tenths of a volt (far below the "decomposition voltage") is applied to platinum electrodes dipping into acidulated water. It might seem from this that Faraday's law is here violated. These slight currents are to be explained, however, by a diffusion of the products liberated slowly and in minute quantities at the electrodes, back into the solution. Currents produced in this manner are called "residual currents" and play an important rôle in the electrolysis of fused salts and probably also in conduction in solid electrolytes. The larger the residual current the less sharply marked is the decomposition point, see *A′*. For many fused salts the current-voltage curve is of the form shown in *B*, Fig. 2. It would be difficult to say from this curve at what voltage decomposition actually began.

Table V gives the experimentally determined decomposition voltages of some of the more common acids, bases and salts.

TABLE V. — DECOMPOSITION VOLTAGES OF NORMAL SOLUTIONS
(*From Le Blanc's Text-book of Electrochemistry, p. 289.*)

Solution	Voltage	Solution	Voltage
Acids:		Bases:	
Dextrotartaric	1.62	Ammonium hydrate	1.74
Dichloracetic	1.66	½ n. diethylamine	1.68
Hydrazoic	1.29	¼ n. methylamine	1.75
Hydriodic	0.52	Potassium hydrate	1.67
Hydrobromic	0.94	Sodium hydrate	1.69
Hydrochloric	1.31	⅛ n. tetramethyl ammonium hydrate	1.74
Malonic	1.69		
Monochloracetic	1.72	Salts:	
Nitric	1.69	$AgNO_3$	0.70
Oxalic	0.95	$CdCl_2$	1.88
Perchloric	1.65	$Cd(NO_3)_2$	1.98
Phosphoric	1.70	$CdSO_4$	2.03
Pyrotartaric	1.57	$CoCl_2$	1.78
Sulphuric	1.67	$CoSO_4$	1.92
Trichloracetic	1.51	$NiCl_2$	1.85
		$NiSo_4$	2.09
		$Pb(NO_3)_2$	1.52
		$ZnBr_2$	1.80
		$ZnSO_4$	2.35

Calculation of Decomposition Voltage from Heat of Reaction. — If the electrolytic process is reversible in the thermodynamic sense, then Gibbs-Helmholtz's equation (*see above*) is directly applicable. Since however the temperature coefficient of the maximum work (or free energy) is known in but

a few instances, one usually employs Thomson's rule, which gives a fair approximation in the case of most commercial processes, even though these processes are not strictly reversible. That is, calling H the heat of formation of the compound which is decomposed into the substances which are liberated at the electrodes (i.e., H is the heat of the reverse reaction corresponding to the complete chemical actions which take place in the cell), the decomposition voltage is

$$E = \frac{H}{230.5\, n},$$

where n = the valency of the ion of highest valency involved in the reaction, and H is expressed in large mean calories per gram-molecule.

Tables giving the voltages required to liberate a number of elements and radicals from various electrolytes computed by Thomson's rule from heats of formation in dilute solutions are given by J. W. Richards in *Jour. Franklin Institute*, 1906.

Example. — In the formation of one mol of solid lead chloride from metallic lead and chlorine gas 828 large mean calories are liberated. The valency of lead is 2; of chlorine, 1. As solid lead chloride does not conduct electricity appreciably at ordinary temperatures, to decompose it electrolytically, it must be either dissolved or fused. If a saturated solution containing an excess of solid lead chloride be electrolyzed, metallic lead will be deposited at the cathode, chlorine gas liberated at the anode, and an equivalent amount of solid lead chloride will pass into solution, the net result then being a decomposition of solid lead chloride into its elements lead and chlorine. Under these conditions the decomposition voltage by Thomson's rule is

$$E = \frac{828}{230.5 \times 2} = 1.79 \text{ volts},$$

as against 1.612 volts by actual measurement.

It should be pointed out that Nernst has recently applied his new heat theorem (*see above*) to the calculation of the e.m.f. of cells similar to the above, with very satisfactory results. Thus the computed value of the e.m.f. in the above case from thermal data by the formula developed by Nernst is $E = 1.594$ volts, in excellent agreement with the observed value. See Nernst's *Theoretical Chemistry*, page 745, 1911 ed.

Calculation of Decomposition Voltage from Electrode Potentials. — Le Blanc was the first to measure by means of a normal electrode the single potential drop at the cathode when various salts were electrolyzed and found that the cathodic drop in potential necessary to discharge a given cation is numerically equal to the electrode potential which would be established if the separated metal were substituted for the actual cathode. For example, to deposit metallic zinc from a normal zinc-sulphate solution it is necessary to impress a potential from solution to electrode as measured against a normal hydrogen electrode of at least 0.77 volt, to overcome the natural rise of potential from the zinc electrode to the solution (as measured by the normal hydrogen electrode) of this amount. See table page 449.

Before continuous electrolysis can begin, however, not only must the applied e.m.f. be sufficient to establish the necessary cathodic drop e_c, but in addition it must also raise the anode potential to a value e_a, corresponding to the electrode potential of the anion which is liberated. If, as is usually the case, several different anions are present in the electrolyte that one will be liberated first which can part with its negative charge with the least expenditure of energy, i.e., at the lowest voltage. It frequently happens that e_c is established long

before e_a is reached, in which case Le Blanc found that e_c remains constant while the impressed voltage E (and hence e_a) is increased up to the decomposition point. The minimum e.m.f. at which decomposition of a given electrolyte begins may therefore be written $E = e_c + e_a$ where e_c and e_a are the cathodic and anodic polarization values produced by that cation and anion respectively which gives up its charge most readily. In an electrolyte containing several different anions and cations all take part in the *conduction* of a current through the solution, but only specific ions are effective in electrolysis, i.e., in giving up their charges to the electrodes.

Overvoltage. — When a gas is evolved at either electrode the above relations are usually more complicated owing to the phenomenon known as overvoltage. Thus in the electrolysis of an acid between polished platinum or other metal electrodes, hydrogen gas is evolved, to liberate which the cathode potential must be raised to a value in excess of that required to liberate hydrogen at a reversible (platinum black) electrode.

This excess of voltage which is necessary to liberate a gas at any electrode over that required to liberate the same gas against a *reversible* gas electrode is called "overvoltage." Its value depends upon the character of the material of the electrode against which the gas is set free and upon the nature of the gas. It is particularly large in the case of hydrogen. In Table VI are given values of the overvoltage for hydrogen as determined by Caspari when this gas is *visibly* set free. The magnitude of the effect is closely related to the power of the metal surface to occlude the gas in question. Thus, platinum and (to a less extent) iron absorb hydrogen readily and hence these metals exhibit slight overvoltage phenomena. Zinc and mercury, on the other hand, have little or no tendency to absorb hydrogen and hence this gas is liberated with great difficulty against cathodes of these metals, with correspondingly high overvoltages. It is for this reason that chemically pure zinc does not readily displace hydrogen from an acid in spite of its high electrode potential.

For theory of overvoltage phenomenon, see Möller, *Ann. d. Physik*, 27, 566, 1908. Also, Crabtree, *Trans. Faraday Soc.*, 1913, Vol. 9, 125.

TABLE VI. — OVERVOLTAGE OF HYDROGEN FOR VISIBLE ELECTROLYSIS.*

Electrode	Over-voltage in volts	Electrode	Over-voltage in volts
Pt, platinized	0.005	Cu	0.23
Au	0.02	Cd	0.48
Fe	0.08	Sn	0.53
Pt, polished	0.09	Pb	0.64
Ag	0.15	Zn	0.70
Ni	0.21	Hg	0.78

Electrolytic Separation of Metals. — The reason that two or more metals can be electrolytically separated from each other by a regulation of voltage follows from the preceding discussion. Consider a solution containing two salts, say silver and copper nitrates, each of normal concentration. If a gradually increasing e.m.f. be applied to inert electrodes dipping into this solution, electrolysis will begin when a voltage is reached sufficient to set free

simultaneously any anions and cations present in the solution. Referring to Table IV, it will be seen that copper stands $0.798 - 0.329 = 0.469$ volt above silver in the electrochemical series, and hence, the latter metal can be deposited from the solution with an e.m.f. nearly half a volt less than copper. No copper ions can separate until the applied e.m.f. has been increased 0.469 volt above that necessary to first separate the silver. The decomposition e.m.f. necessary will, of course, depend on the nature and concentration of the anions present. As electrolysis proceeds, the solution becomes weaker and weaker with respect to silver ions and the voltage necessary to separate them from the solution increases. If the electrolysis is continued until the silver remaining in solution has a concentration only 1/1,000,000 that at the start (the limit of analytical determinations), the change in voltage will be approximately 0.34 volt (*see section above on Variation of Electrode Potentials with Concentration*). This is still insufficient to bring the applied e.m.f. up to a value sufficient to permit the copper to deposit, and hence, silver and copper may be completely, for all practical purposes, separated from each other.

It is to be noted that as the electrolysis proceeds and the silver is removed from the solution a greater and greater percentage of the current is *conducted* by the copper. The solution in the neighborhood of the cathode becomes continually weaker with respect to silver ions. In a quiet electrolysis the silver ions at the cathode are replenished by diffusion from the interior of the electrolyte. This process may be greatly accelerated by violently stirring the solution, as, for example, by the use of a rapidly rotating electrode. This permits good deposits being obtained with higher current density and greatly reduces the time required for the separation.

Secondary Reactions. — In the preceding sections the principles underlying *primary* electrolysis have been explained. The ultimate products which are produced at the anode and cathode are often quite different from the simple ions or ionic complexes liberated by the action of the current. In general, the primary process of discharge of ions at cathode and anode is followed by a secondary reaction of one of the following types:

1. The discharged ions form molecules, e.g.:

At cathode $2\,H = H_2$ gas,
At cathode $x\,Cu = Cu_x$ solid,
At anode $2\,Cl = Cl_2$ gas.

This may occur at both anode and cathode.

2. The discharged ions react with each other or break up, e.g.:

At anode $2\,OH = H_2O + \frac{1}{2}\,O_2$,
At anode $\begin{matrix} COO \\ | \\ COO \end{matrix} = 2\,CO_2$,
At anode $2\,CH_3COO = 2\,CO_2 + C_2H_6$.

This is very characteristic at the anode, particularly of organic anions.

3. The discharged ions react with the solvent, e.g.:

At cathode $Na + H_2O = NaOH + \frac{1}{2}\,H_2$,
At anode $SO_4 + H_2O = H_2SO_4 + \frac{1}{2}\,O_2$.

4. The discharged ions react with the solute, e.g.:

At cathode $8\,H + 2\,H_2SO_4 = H_2SO_3 + S + 5\,H_2O$,
At cathode $K + KAg(CN)_2 = Ag + 2\,KCN$.

5. Discharged ions react with the electrode, e.g.:

At cathode $4\,H + PbO_2 = Pb + 2\,H_2O$,
At anode $2\,Cl + Cu = CuCl_2$.

Which of the above reactions is most likely to occur in any given case depends to some extent upon, (a) current density; (b) temperature; (c) concentration of the solution.

In general, it may be said that at the cathode a reduction takes place, while at the anode oxidation (in its general sense) occurs. The intensity of these reactions depends upon the electrode potential at which the reaction takes place. This can be varied by the use of different electrode materials (thereby increasing the overvoltage). The efficiency of certain secondary reactions has also been found to depend upon the nature of the electrode (catalytic action). The efficacy of electrolytic reduction and oxidation in organic chemistry where the intensity of the reaction must be carefully regulated likewise rests on the above factors.

Passivity. — A metal is said to assume the "passive" state when it comports itself towards acids like a noble metal, i.e., becomes insoluble. Iron affords a very striking example of this phenomenon, although it is exhibited by other metals as well. Thus, if dipped in strong nitric acid, or if anodically polarized, it becomes passive. Two explanations have been advanced to account for the phenomenon, one that it is due to an invisible film of oxide on the surface, and the other that the surface assumes a condition in virtue of which the velocity of reaction between it and the surrounding solution is infinitely slow.

Alternating-current Electrolysis. — The decomposition of an electrolyte, and the solution of metal electrodes by electrolysis, can be effected under certain conditions by an alternating current as well as by a direct current. The chief determining factors are the velocity with which the chemical reaction accompanying the electrolysis takes place and the periodicity of the alternating current.

THEORY OF SOLUTIONS. — To understand the theory of the various phenomena described above, a knowledge of the theory of solutions is necessary.

Osmotic Pressure. — The present theory is based upon Van't Hoff's thermodynamic and experimental investigations published in 1887. When a substance is brought into contact with a second substance in which it is more or less soluble, it dissolves in virtue of a force (the nature of which is imperfectly understood), which is called its "solution tension" or "solution pressure." If the solute is present in excess, the process of solution continues until the solution becomes saturated, i.e., until equilibrium is established between the solute and solution, such that the solution pressure of the former is just balanced by an opposing pressure created within the solution which tends to cause the dissolved substance to separate out. This pressure is called the osmotic pressure of the solution. Under these conditions there are just as many molecules of solute passing into solution as separate out of the solution during any interval of time. A clearer conception of the osmotic pressure of a solution, as above defined, may be obtained from the following considerations.

Semi-permeable Membranes. — If a solution be placed at the bottom of a cylinder and carefully covered with a layer of pure solvent, the process of diffusion will begin at once and continue until a homogeneous dilute solution is formed. If the experiment be repeated with the single modification, that the pure solvent is separated from the solution by a piston consisting of a semi-permeable diaphragm which will permit the solvent to pass freely through it in either direction, but which will not allow the solute to pass through, the process of diffusion will take place as before, provided the piston is movable. Thus the piston will be forced back by the osmotic pressure of the solution while the solvent passes freely through it thereby diluting the solution. Membranes possessing the property of semi-permeability are not only theoretically con-

ceivable but may actually be prepared. Such a membrane is formed by the precipitate of copper ferrocyanide formed within the walls of an unglazed porous cell when copper sulphate and potassium ferrocyanide solutions are allowed to diffuse into the cell from within and without respectively. This membrane is permeable to water, but impermeable to sugar and many other organic and inorganic substances, such as the copper and potassium salts from which it is formed. Most membranes, in fact, possess the property of semi-permeability to a limited degree.

Measurement of Osmotic Pressure. — To prevent the piston being forced up by the diffusing solution, a downward pressure P must be applied to it equal to that exerted upon it from below by the solution. The magnitude of P is, therefore, a measure of the osmotic pressure of the solution. Owing to experimental difficulties, it is impracticable to measure osmotic pressures in precisely the manner just described, but by slightly modifying the arrangement of the apparatus it may readily be done. Thus, if the solution is contained in a closed vessel, A, Fig. 3, the walls of which are made semi-permeable by depositing a membrane of copper ferrocyanide within the pores of the cell, and this be immersed in the solvent B, the osmotic pressure will be exerted as before against the membrane from within. If the latter could stretch like a rubber balloon, it would do so as the solution became diluted; being, however, restrained by the material of the walls of the cell on and in which it is deposited from doing this, dilution of the solution can take place only by the solvent passing through the fixed membrane into the solution cell. This it will do unless the cell A is hermetically sealed. If an open manometer M of small bore be inserted in the top of A, the solvent as it passes into the cell will cause the solution to rise gradually in M until the hydrostatic pressure thus produced prevents further entrance of solvent. When equilibrium is established, the hydrostatic pressure gives a measure of the osmotic pressure of the solution then existing in the cell. As the entrance of an appreciable amount of solvent into the cell reduces the concentration of the solution, the pressure thus measured is less than that of the original solution; hence for quantitative work an open manometer is replaced by a closed mercury manometer.

Fig. 3.

Laws of Osmotic Pressure in Non-electrolytic Solutions. — By an apparatus similar in principle to that just described the following laws have been verified. They hold for aqueous solutions of many organic substances, such as sugar, and for many solutions in organic solvents, all of which possess the common property of being non-electrolytes.

1. The osmotic pressure of a solution is directly proportional to its concentration (and therefore inversely proportional to the volume in which a given mass of the solute is dissolved).

2. It is directly proportional to the absolute temperature.

3. It is independent of the nature of the solute, being a function solely of the number of mols of substance dissolved in unit volume of solution.

4. The numerical magnitude of the osmotic pressure p of one mol of any substance dissolved in a volume v of solution at the absolute temperature T is identical with the gaseous pressure exerted by one mol of a perfect gas at the temperature T and occupying the same volume v.

The gas laws are therefore not only directly applicable to solutions, but the numerical value of the gas constant R is the same for each. Thus the combined laws of Boyle and Gay-Lussac for gases have the same form for solutions, namely

$$pv = RT,$$

where p = the osmotic pressure, v = the volume of the solution containing one mol of solute, and T = the absolute temperature.

The accompanying table gives the numerical value of $\bar{R}$ when the various quantities are expressed in the units designated. In heat units

$$\bar{R} = 1.985 \frac{\text{calories}}{\text{deg. cent.}}.$$

Abs. pressure p	Volume v	Abs. temp. T	Gas constant $\bar{R}$
Atmospheres	Liters	Deg. cent.	0.0821
Grams per sq. cm.	Cu. cm.	Deg. cent.	84,800
Dynes per sq. cm.	Cu. cm.	Deg. cent.	0.83161×10^8

When applied to concentrated solutions of non-electrolytes the above laws suffer deviations analogous to those which they exhibit when applied to highly compressed gases.

Osmotic Pressure in Electrolytic Solutions. — The first of the above laws for non-electrolytic solutions applies to electrolytic solutions only within narrow limits, while the third and fourth laws fail absolutely. The osmotic pressure of this class of solutions is much greater than the equation $pv = \bar{R}T$ would lead one to expect. Thus, a 0.1 normal sodium chloride solution has an osmotic pressure 1.9 times as great as that which it should have on the basis of the above formula. A potassium sulphate solution containing 0.1 gram-equivalent per liter has an osmotic pressure 2.3 times as great as that calculated. To bring these results within the scope of the gas-law formula, Van't Hoff proposed the empirical equation $pv = i\bar{R}T$, where i is a constant having the value unity for non-electrolytes and a value greater than unity for electrolytes.

THE DISSOCIATION THEORY. — Arrhenius, in 1887, gave the first satisfactory explanation of the anomalous behavior of electrolytes, which show not only abnormally high osmotic pressures, but also abnormally high boiling points and abnormally low vapor pressures and freezing points. On thermodynamic principles these phenomena can all be shown to be proportional to the total number of molecular complexes per unit volume and entirely independent of their chemical constitution. Abnormally high osmotic pressures may therefore be explained on the assumption that each molecule, when dissolved, exists in a more or less dissociated condition, i.e., at any given instant there are in the solution more discrete particles or complexes than there would be if each molecule remained continuously intact. The ions are not supposed to be permanently separated, but a continuous process of dissociation and combination is assumed to be going on all the time. If the further assumption be made that the dissolved substance is electrolytically active only during that fraction of time while it exists in a dissociated or ionized state, in other words, that dissociated molecules are alone capable of being acted upon by electric forces, the connection between electrolytes and solutions showing deviations from the gas laws is explained.

On the assumptions of this theory, sodium chloride, NaCl, in aqueous solution is partially dissociated or ionized according to the equation, $NaCl \rightleftarrows \overset{+}{Na} + \overset{-}{Cl}$, and therefore at any instant there are present in the solution not only sodium-chloride molecules, but also positively charged sodium ions and an equal number of negatively charged chlorine ions, the number of which at any instant depends upon the average fraction of a second during which the molecules are dissociated or "ionized." If the salt were "completely, i.e., 100 per cent ionized" there would be no molecules, as such, present in the solution, but instead twice the number of ions as there were molecules originally dissolved. Hence the

from the equation $pv = \bar{R}T$; in equation $pv = i\bar{R}T$, i would be equal to 2. Again, if a given volume of solution contains one mol of potassium sulphate, K_2SO_4, which is 75 per cent ionized according to the equation $K_2SO_4 \rightleftarrows 2\overset{+}{K} + \overset{-}{SO_4}$, then at any instant there will be $1 - 0.75 = 0.25$ mol of K_2SO_4 molecules, 0.75 mol of $\overset{-}{SO_4}$ ions, and $2 \times 0.75 = 1.50$ mol of $\overset{+}{K}$ ions present in the solution, or $0.25 + 0.75 + 1.50 = 2.5$ molecular complexes for every mol of sulphate dissolved; hence $i = 2.5$.

Although the nature of the ions resulting from the ionization of acids, bases and salts is now known to be more complicated in many cases than assumed in such simple ionization reactions as the above, owing to their association with molecules of the solvent, still the above hypothesis of Arrhenius has proved the most fruitful conception which has been introduced into chemistry during the last twenty-five years and it remains to-day, modified somewhat in the light of recent research, the best working hypothesis with which to interpret electrolytic phenomena in aqueous solutions. It is a natural sequel to the free ion theory of Clausius which in turn displaced the old chain theory of Grotthuss.

THEORY OF ELECTROLYTIC CONDUCTION. — The external effects of a current flowing through an electrolyte cannot be distinguished from those produced by a current of the same strength conducted by a metal. Thus the magnetic effect of a current flowing through a helical glass tube filled with electrolyte is the same as that produced by the same current flowing through an equivalent circuit of an equal number of turns of copper wire. A current may be induced in a closed ring of electrolyte just as in a ring of metal. Ohm's Law and Joule's Law hold for conduction in electrolytes as well as in metals. The mechanism of the conduction in the two cases, however, is very different, as shown by the phenomena produced at the junction of two conductors in one of which the conduction is metallic or "electronic" and in the other of which it is electrolytic or "ionic."

Migration of Ions. — Electrical conduction, both metallic and electrolytic, is believed to be a convection phenomenon. In the case of electrolytic conduction there is much evidence to indicate that the convection consists in the transport of electrically charged ions through the electrolyte, both with and against the direction in which the current is assumed to flow. Simultaneous convection of anions and cations in opposite directions may not only be made visible to the eye but their velocities may also be directly measured. On the assumption that the ions are the carriers of charges, the motion of which constitutes the current, the velocity of "migration" can also be calculated from conductivity measurements and the experimentally determined "transport ratios" (*see below*).

Velocity of Migration. — In Table VII are given the results of direct measurements of the migration velocity of various ions and also the calculated velocities, both expressed in centimeters per second and for a potential gradient of one volt per centimeter.

The velocities are directly proportional to the potential gradient. They all increase rapidly with the temperature. They vary but slightly with the concentration of the solution if the concentration is not too great, and for dilute solutions may be regarded as practically constant.

From the table it is seen that hydrogen migrates with the maximum velocity. Hydroxyl $\overset{-}{OH}$ has the next greatest velocity. The high velocity of the hydrogen ion explains the fact that aqueous solutions of the mineral acids are as a class the best electrolytic conductors, and the high velocity of the hydroxyl ion accounts for the relatively good conductivity of the inorganic bases.

As the velocity with which an ion migrates under the action of a given force depends upon the friction which it has to overcome in moving through the solution, an intimate relation should be expected between it and the rate of diffusion and fluidity (reciprocal of viscosity) of the solution. The viscosity of a solution diminishes or its fluidity increases rapidly with an increase in temperature (from one to two per cent per degree) and experiment shows that the migration velocity increases at approximately the same rate. The increased velocity of migration of the ions with rising temperature is the cause of the high temperature coefficients of electrolytes.

TABLE VII. — VELOCITIES OF MIGRATION OF IONS

Ion	Velocities in cm. per sec. per volt per cm.		
	0.1 gram-equivalent per liter, 18° C.		Infinite dilution, 18° C.

Transport Ratio. — When a current passes through an electrolytic solution a change in concentration is found to take place in the immediate vicinity of the anode and cathode, but practically no change takes place in the middle portion of the solution, provided means are employed to prevent convection and diffusion from the electrodes. Suppose that the solution about the anode and cathode respectively is analyzed after a known current has passed for a known time.

Let

a = number of gram-equivalents of the *solute* which disappear from the region about the anode,

c = number of gram-equivalents of the *solute* which disappear from the region about the cathode,

then $a + c$ = total number of gram-equivalents of the solute which is decom-

The ratio $n_a = c/(a + c)$ is called the transport ratio for the anion and the ratio $n_c = 1 - n_a = a/(a + c)$ is called the transport ratio for the cation. These ratios are also frequently referred to as "Hittorf's transference numbers." For a given electrolyte n_a is proportional to the number of gram-equivalents of the anions which migrate through the solution from the cathode towards the anode and n_c to the number of gram-equivalents of the cations transported from the anode towards the cathode.

On the assumption that the ions are the sole carriers of the charges the motion of which constitutes the electric current, the ratio of the current carried by the anions or cations to the total current is the same as the above transport ratio for these ions, since the charge carried by one gram-equivalent of every ion is constant = 96,540 coulombs.

TABLE VIII.—TRANSPORT RATIOS n_a OF ANIONS IN AQUEOUS SOLUTIONS AT ABOUT 18° C.

(Values in parenthesis are somewhat uncertain. From Le Blanc's *Electrochemistry.*)

Gram-equivalents per liter	0.01	0.05	0.2	1	2	5

½ $CdSO_4$	0.616	0.635	0.672	0.746	.....	.....
½ $MgSO_4$	0.620	0.633	(0.66)	0.74	(0.76)	.....
½ $CuSO_4$	.....	0.625	0.657	.....	.....	.....
½ H_2SO_4	0.176	0.175	.....	.....	.....	.....

Note.—The ½ before the various bivalent electrolytes indicates that 1 gram-equivalent = ½ mol.

Table VIII contains the generally accepted values of the transport ratios for the more common ions. These numbers vary but slightly with the temperature. They tend to approach the value 0.5 with increasing temperature, i.e., as the temperature rises both ions of a given electrolyte tend to conduct equal per cents of the current. With increasing dilution the transport ratios of good electrolytes approach constant limiting values; these are practically reached in solutions whose concentration is 0.01 gram-equivalent per liter.

Relation between Velocity of Migration and Transport Ratios. — On the assumption that the ions are the carriers of the charges the motion of which constitutes the electric current, and on the further assumption that the moving ions do not carry along with them different quantities of the solvent, the ratio of the velocity u_a of the anions to the velocity u_c of the cations in any solution must be equal to the ratio of the transport ratios $n_a = c/(a+c)$ and $n_c = a/(a+c)$ of the anions and cations respectively, i.e.,

$$\frac{u_a}{u_c} = \frac{n_a}{n_c} = \frac{c}{a}.$$

The transport ratios n_a and n_c may be determined experimentally as described above and by the use of this relation the *relative* velocities of migration may be compared with the ratio calculated from the direct determination of the velocities u_a and u_c.

Hydration or Solvation of Ions. — The above relation between the velocities of migration and the transport ratios has been found to hold only approximately in a number of instances. A possible explanation of this lack of agreement between theory and experiment is that the changes in concentration at the two electrodes are due not only to the migration of the ions of the solute from one electrode to the other, but that the ions carry along with them molecules of the solvent, the amount of solvent carried by the anions and cations being different. This "hydration" or "solvation" of the ions has recently been proved by direct experiment (*Washburn, Zeit. für Phys. Chem., Vol. 66, p. 513, 1909*), by adding to the solution an indifferent substance upon which the electric current produces no migratory effect (e.g., sugar or raffinose). See also Lewis, J., *Am. Chem. Soc., Vol. 32, p. 862, 1910.*

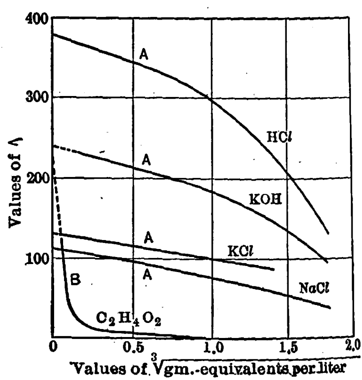

Fig. 4.

Conductance of Electrolytes. — (*See also article on Resistance and Conductance.*) While no simple relations have been found to hold between the *specific* conductances of different electrolytic solutions, very important results follow at once from a comparison of their *equivalent* conductances.

Table IX shows the relation between the equivalent conductance Λ and the concentration m in gram-equivalents per liter for some typical aqueous solutions. In Fig. 4 certain of these data are shown graphically. From a study of these results the following important conclusions may be drawn.

TABLE IX. — EQUIVALENT CONDUCTANCE Λ OF TYPICAL ELECTROLYTES DISSOLVED IN DIFFERENT QUANTITIES OF WATER, AT 18° C.

Note. — The ½ before $CuSO_4$ and H_2SO_4 indicates 1 gram-equivalent = ½ mol.

For complete tables consult *Landolt and Börnstein's* or *Kohlrausch and Holborn's Tables.*

1. The Equivalent Conductance of a Solution Increases as the Dilution of the Solution Increases and Approaches a Limiting Maximum Value. — The maximum equivalent conductance, usually denoted by Λ_∞, is different for different solutions. It may be found graphically for good electrolytes (giving curves of the form A, Fig. 4), by extrapolating the curve representing the observed data until it cuts the ordinate of zero concentration. This method fails however for weak electrolytes such as acetic acid, see Curve B.

2. Independent Migration of Ions. Ionic Mobilities. — The product of the equivalent conductance of any solution at infinite dilution Λ_∞ and the transport ratio of either of the ions forming the electrolyte is a constant for that ion and independent of the nature of the electrolyte. That is, calling n_a and n_c the transport ratios of the anions and cations respectively, the product $l_a = n_a\Lambda_\infty$ is a constant irrespective of the nature of the electrolyte of which this anion forms a part; similarly $l_c = n_c\Lambda_\infty$ is a constant for the cation irrespective of the nature of the electrolyte of which it forms a part. For example, the product $n_c\Lambda_\infty$ for the potassium ion is a constant whether the solution be one of potassium chloride, potassium bromide, potassium sulphate, etc. These constants l_a and l_c are called the "mobilities" or "ionic conductivities" of the ions. This relation was discovered by F. Kohlrausch in 1876 and stated as the law of the independent migration of ions.

Since, by definition, $n_a + n_c = 1$, it follows that

$$\Lambda_\infty = l_a + l_c.$$

In other words the maximum equivalent conductivity of a solution (at infinite dilution) is equal to the sum of the mobilities of the anions and cations which form the electrolyte; or, the mobility of an ion depends solely upon the nature of the ion and not upon the nature of the substance of which it originally formed a part.

From this relation the mobility of any ion may be determined directly from the equivalent conductance when the mobility of the ion with which it is associated is known.

The values of the mobilities of the more common ions at 18° C. and at infinite dilution are given in Table X. From this table the equivalent conductance of any given electrolyte at infinite dilution may be readily calculated by the formula $\Lambda_\infty = l_a + l_c$. Thus, for silver nitrate, $AgNO_3$, at 18° C. $\Lambda_\infty = l_{Ag} + l_{NO_3} = 54.3 + 61.7 = 116.0$.

TABLE X. — MOBILITIES OF TYPICAL IONS AT INFINITE DILUTION AND 18° C.

(Values at $t°$ may be computed by the formula $l_t = l_{18}[1 + \alpha(t - 18) + \beta(t - 18)^2]$)

The mobilities at any other dilution ϕ may also be determined in the same way from a measurement of the conductivity Λ_ϕ at this dilution and the corresponding transport ratios n_a and n_c, but the product $n_a\Lambda_\phi$ or $n_c\Lambda_\phi$ for ions in fairly concentrated solutions is not independent of the nature of the electrolyte.

Interpretation of the Laws of Electrolytic Conduction on the Dissociation Theory. — The interpretation of the above experimental facts in the light of the dissociation theory is simple. On this theory, the value of Λ_ϕ is

determined by three factors, any one of which, if zero, will make $\Lambda_\phi = 0$. These are:

1. The fraction of the total number of molecules in one gram-equivalent of the solute which are dissociated at any instant. This fraction, called the "degree of ionization" or "ionization coefficient," is usually denoted by γ_ϕ, the subscript ϕ indicating the dilution to which it refers.

2. The average velocities with which the ions migrate while free. Let u_c and u_a be these velocities, in centimeters per second, for the cations and anions respectively, for a potential gradient of one volt per centimeter.

3. The charge carried by the ions. This is fixed, since one equivalent weight of every ion carries with it $F = 96{,}540$ coulombs.

If a volume ϕ of the solution containing one gram-equiv. of the solute be imagined placed between two parallel plate electrodes 1 cm. apart, and an e.m.f. of one volt be applied, the quantity of electricity conducted across the electrolyte in one second, i.e., the current, will be equal to the equivalent conductance Λ_ϕ (definition of Λ_ϕ). The current is also equal to the total quantity of electricity conducted by the cations plus that conducted by the anions; hence

$$\Lambda_\phi = \gamma_\phi F u_a + \gamma_\phi F u_c = \gamma_\phi F\,(u_a + u_c).$$

The experimental fact that for many electrolytes at infinite dilution Λ_ϕ is equal to the sum of two constants l_a and l_c (the mobilities of the ions) which depend only on the nature of the ions, indicates that the velocity of migration u_a or u_c of any given ion depends only upon the nature of the ion and not upon the electrolyte of which it forms a part, and that the degree of ionization at infinite dilution is the same for all such solutions; there is much evidence to indicate that this is practically 100 per cent (*see below*).

Degree of Ionization. — The fact that Λ_ϕ increases with the dilution may be due either to the velocities u_a and u_c or to γ_ϕ increasing with the dilution, or to both causes combined; F is a constant. In concentrated solutions both the velocities and the degree of ionization undoubtedly decrease as the concentration increases. For dilute solutions, however, there is considerable evidence to show that the frictional resistance opposed to the motion of the ions changes but slightly with increasing dilution, and hence the values of the migration velocities in such solutions may be regarded as nearly constant. If this be assumed, and also that the *nature* of the ions remains unchanged, i.e., that u_c and u_a at the dilution ϕ are practically the same as at infinite dilution, $\phi = \infty$, then the observed increase in Λ_ϕ with the dilution must be due to an increase in γ_ϕ. On these assumptions, the solute becomes more and more ionized as the dilution increases, and at infinitely great dilution all the molecules of the solute are continuously dissociated or ionized, i.e., as ϕ approaches infinity, γ approaches unity.

Hence for $\phi = \infty$, $\Lambda_\infty = F\,(u_c + u_a)$, and therefore

$$\frac{\Lambda_\phi}{\Lambda_\infty} = \frac{\gamma_\phi F\,(u_c + u_a)}{F\,(u_c + u_a)} = \gamma_\phi.$$

This relation affords the simplest way of determining the coefficient of ionization γ_ϕ of an electrolyte, namely, finding the ratio of its equivalent conductance at dilution ϕ to its maximum conductance at infinite dilution. The two assumptions mentioned above should not be lost sight of when applying this formula. The values of γ_ϕ thus computed for a number of typical electrolytes are given in Table XI. The results obtained by this method are in many cases in excellent agreement with the values of ionization coefficients obtained by

methods independent of all electrochemical considerations, such as the lowering of the freezing point of a solution.

TABLE XI. — IONIZATION COEFFICIENTS OF TYPICAL ELECTROLYTES AT VARIOUS DILUTIONS COMPUTED FROM RATIO $\frac{\Lambda_\phi}{\Lambda_\infty} = \gamma_\phi$

(Kohlrausch and Holborn's data)

Liters per gm.-equivalent $= v = \frac{1}{1000}\phi$	Gm.-equivalents per liter $= m = 1000\,\eta$	NaCl	HCl	KOH	½$CuSO_4$	NH_4OH	$C_2H_4O_2$
1	1	0.675	0.784	0.770	0.217	0.0037	0.0036
10	0.1	0.839	0.914	0.891	0.379	0.0139	0.0131
100	0.01	0.933	0.964	0.954	0.608	0.0403	0.0406
1000	0.001	0.978	0.982	0.979	0.856	0.118	0.117

Note.—The ½ before the $CuSO_4$ indicates that 1 gram-equivalent of H_2SO_4 = ½ mol. of H_2SO_4.

Calculation of Velocity of Migration of Ions. — From a knowledge of the mobility of an ion its actual velocity of migration may be easily computed on the assumptions of the dissociation theory. Thus for aqueous solutions at infinite dilution, in which the ionization may be assumed complete, $l_c = Fu_c$ and $l_a = Fu_a$; hence $u_c = \frac{l_c}{F}$ and $u_a = \frac{l_a}{F}$. From Table X we have for the sodium ion $l_{Na} = 43.5$ and for the chlorine ion $l_{Cl} = 65.5$; therefore the velocity in centimeters per second per volt per centimeter with which these ions migrate at 18° C. is $\frac{43.5}{96,540} = 0.000450 \frac{\text{cm.}}{\text{sec.}}$ and $\frac{65.5}{96,540} = 0.000677 \frac{\text{cm.}}{\text{sec.}}$ respectively. For other dilutions the degree of ionization must be taken into account. The values given in Table VII are obtained in this way. For the relation of velocity of migration to diffusion phenomena see Nernst's *Theoretical Chemistry, p. 368; Trans., 6th Ed., 1911.*

Effect of Concentration on Degree of Ionization. — It has been pointed out that the concentration of a solution has relatively little effect on the velocity with which the ions migrate, except at high concentrations. Hence the large increase of the equivalent conductance with the dilution ϕ, see *Fig. 4, and Table IX*, must be due to a change in the degree of ionization. It can be shown on theoretical grounds that the ionization coefficient γ of a binary electrolyte should vary with the dilution ϕ or concentration η according to the equation

$$\frac{\gamma^2}{\phi(1-\gamma)} = K \quad \text{or} \quad \frac{\eta\gamma^2}{1-\gamma} = K,$$

in which K is a constant called "the equilibrium constant of the ionization reaction," for the given temperature and pressure. This formula, known as "Ostwald's Dilution Law," holds exactly only for weak electrolytes, i.e., those which are slightly ionized like the organic acids, and which give rise to dilution curves of the type *B, Fig. 4.* For good electrolytes, giving curves of the type *A*, the formula fails completely. A wholly satisfactory explanation for this discrepancy has not yet been given. (*See discussion in recent address by James*

Walker, British Association Meeting, 1911. Also G. N. Lewis, Zeit. f. physik. Chem., 70, 216, 1910.) Instead of obeying the above law, curves of the type *A* satisfy an exponential equation of the form

$$\frac{(\eta\gamma)^n}{\eta\,(1-\gamma)} = \text{constant},$$

in which n is a constant depending upon the electrolyte and having a value between 1.40 and 1.56. Other "dilution laws" have also been proposed by Kohlrausch, Van't Hoff, Rudolphi, Kraus and Bray.

Effect of Temperature on Ionization. — The per cent to which a substance is ionized in solution may increase or decrease with the temperature. The sign and magnitude of the effect depend upon whether the ionization reaction is accompanied by an absorption or evolution of heat. Substances which dissociate with evolution of heat become less ionized with increasing temperature; substances which dissociate with absorption of heat become more ionized with rising temperature. Highly dissociated substances like sodium chloride, hydrochloric acid, etc., belong to the former class. Water which is very slightly ionized belongs to the latter class. In general a variation of temperature from 0° to 100° C. produces a change in ionization of only a few per cent. Recent investigations by Noyes carried out at temperatures up to 360° C. have confirmed these predictions of theory. The effect of temperature on γ may be computed through its effect on K by means of Van't Hoff's thermodynamic relation

$$\frac{d \log K}{dt} = \frac{Q}{\overline{R}T^2},$$

where K is the above equilibrium constant of the ionization reaction, Q the heat of the corresponding reaction, $\overline{R}$ the gas constant and T the absolute temperature to which the values of K and Q refer. For derivation of this equation see Nernst's *Theoretical Chemistry, page 659, 1911 Ed.*

Negative Temperature Coefficients of Electrical Conductivity. — The fact that certain electrolytes, e.g., a phosphoric-acid solution, may have a negative temperature coefficient is readily explained in terms of the above relations. If the increase in the velocity of migration of the ions with rising temperature is more than offset by a diminution in the average number of free ions, resulting from a decrease in ionization, the conductivity of the solution will diminish. By combining solutions having positive and negative temperature coefficients in suitable proportions, electrolytes have been prepared which have nearly a zero temperature coefficient over quite a range of temperature. The following mixture, proposed by Manganini, has this property: 121 grams mannite, 41 grams boracic acid, 0.06 gram potassium chloride dissolved in sufficient water to make one liter. Its specific conductance at 18° C. is $\kappa = 0.00097$. Such a solution is well adapted for a liquid resistance just as manganine wire is adapted for resistance coils.

Conductivity of Fused Electrolytes. — In Table XII are given the specific conductance (κ) and the equivalent conductance (Λ) of several typical fused salts at their respective melting points; also for comparison the equivalent conductance of these salts in infinitely dilute aqueous solutions at 18° C. It will be seen that the values of the specific conductance (κ) of the salts at their respective melting points are much greater than the values of the specific conductance of the same salts in normal aqueous solutions. On the other hand, if the volume ϕ occupied by one gram-equivalent of the salts in the fused state is determined by specific gravity measurements and the equivalent conductance Λ computed ($\Lambda = \phi\kappa$), it will be seen that these values are less

than the maximum equivalent conductance Λ_∞ of the same salt in aqueous solutions. Thus the conducting power of one equivalent of fused sodium nitrate at 305° C. is less than when the same weight of salt is dissolved in one or more liters of water.

TABLE XII. — SPECIFIC AND EQUIVALENT CONDUCTANCE OF TYPICAL FUSED SALTS AT THEIR MELTING POINTS

Salt	Temperature, melting point, °C.	Specific conductance, κ	Equivalent conductance, Λ	Λ_∞ at 18° C. in aqueous solution
$NaNO_3$	305	0.9510	42.15	105.2
KNO_3	334	0.6225	33.59	126.3
$LiNO_3$	250	0.7886	30.36	95.1
$AgNO_3$	218	0.6815	29.22	116.0
$AgClO_3$	215	0.3676	18.09	109.3

If electrical conduction in fusions is wholly electrolytic it is probable that it is determined by the same three factors which determine the conductance of solutions, and that the equivalent conductance may be expressed by an equation of the general form

$$\Lambda = \gamma F\,(u_c + u_a).$$

As yet, however, all attempts to measure the velocity with which ions migrate in fused salts have led to no satisfactory or conclusive results. Hittorf's transference ratios cannot be determined as in solutions, since in a pure fused salt concentration differences do not occur at the electrodes. Only indirect estimates of the value of γ have been possible. The evidence thus far obtained, however, points to a high rather than to a low state of ionization in molten salts. For a résumé of the present status of this question see Goodwin, *Trans. Am. Electrochem. Soc.*, *1912*.

The equivalent conductance of fused salts increases in general from 1 to 1½ per cent per degree centigrade. As the increase has been found in a number of cases to be almost identical with the increase in the fluidity of one equivalent weight of the fused mass, it is probable that the velocity of migration of the ions increases in this proportion. The ionization of fused salts is certainly not a result of temperature, as in the case of gases; there is evidence, in fact, that the ionization of some fused salts may decrease with increasing temperature as it does in their aqueous solutions.

THEORY OF CONTACT POTENTIALS. — In the case of liquid-liquid junctions and metal-liquid junctions a satisfactory theory, based on the dissociation theory and the theory of solutions, has been worked out.

Theory of Liquid-liquid Potentials. — Nernst (*Zeit. für Phys. Chem.*, *4, page 129, 1889*) was the first to show that in the case of electrolytes a difference of potential necessarily arises between two solutions in contact which gradually diminishes, until the solutions are completely mixed. The general theory, worked out by Planck (*Ann. der Physik, Vol. 40, page 561, 1890*) is complicated. It leads, however, to simple formulæ in the following special cases.

Case I. — The junction is between two dilute solutions of the *same solute at different concentrations* c_1 and c_2, both ions of the solute having the valency n;

for example, c_1-HCl — c_2-HCl or c_1-$ZnSO_4$ — c_2-$ZnSO_4$. The potential rise between solutions 1 and 2 is given by the equation

$$e = \frac{\bar{R}T}{nF}\frac{l_c - l_a}{l_c + l_a}\log_\epsilon\frac{c_1}{c_2}$$
$$= \frac{0.000198}{n}T\frac{l_c - l_a}{l_c + l_a}\log_{10}\frac{c_1}{c_2}\text{ volts,}$$

where $\bar{R}$ = the gas constant; T = absolute temperature; F = the Faraday = 96,540 coulombs; n = valence of ions; l_c and l_a the mobilities of the cations and anions, respectively; and c_1 and c_2 the concentrations (or, more exactly, the corresponding osmotic pressures) of the ions in the two solutions respectively.

It follows from this formula that the potential at a liquid junction approaches zero if the electrolyte is composed of two ions which migrate with nearly equal velocities, and increases as the difference in their velocities increases. Thus $\overset{+}{K}$ and $\overset{-}{Cl}$ ions have nearly identical mobilities, and hence between any two solutions of potassium chloride there exists only a very small potential difference. For a concentration ratio of 10 to 1 the potential difference at 18° C. is only 0.0004 volt. This theory also explains why liquid-liquid potentials are greatest between acids or between alkali solutions, for hydrogen and hydroxyl ions possess relatively great mobilities.

Case II. — The liquid junction is between solutions of two *different solutes*, each containing two ions of the same valence n and at the *same concentration*. Here again the process of diffusion gives rise to potential difference between solution 1 and solution 2, the value of which may be computed by the formula

$$e = \frac{\bar{R}T}{nF}\log_\epsilon\frac{l_{c_2} + l_{a_1}}{l_{c_1} + l_{a_2}}$$
$$= \frac{0.000198\,T}{n}\log_{10}\frac{l_{c_2} + l_{a_1}}{l_{c_1} + l_{a_2}}\text{ volts,}$$

where l_{c_1}, l_{a_1} and l_{c_2}, l_{a_2} are the mobilities or migration velocities of the cations and anions in the two solutions respectively. The above formulæ as well as the general formula for mixed electrolytes have been satisfactorily verified by experiment.

For most recent work see *Trans. Faraday Soc. Vol. 8, p. 86, 1912.*

Theory of Metal-liquid Potentials. — By extending the conception of the process of solution of solids in liquids to the case of metals, which pass into solution only as positively charged ions, Nernst (*Zeit. f. Phys.-Chem.*, 4, 129, *1889*) developed an osmotic theory of metal-liquid potentials. This applies to all kinds of electrodes which are reversible in the thermodynamic sense, or which from an experimental standpoint are non-polarizable. For all such reversible electrodes Nernst has shown that the potential from metal to liquid may be expressed by the relation

$$e = \frac{\bar{R}T}{nF}\log_\epsilon\frac{P_M}{p}$$
$$= \frac{0.000198}{n}T\log_{10}\frac{P_M}{p}\text{ volts,}$$

where again $\bar{R}$ is the gas constant, T the absolute temperature, n the valence of the metal ions, F the Faraday, p the partial osmotic pressure of the metal ions present in the solution and P_M a constant characteristic for each metal, which depends upon the temperature and solvent, but is independent of the nature of the solute.

Electrolytic Solution Pressure. — The constant P_M in the above formula is called the "electrolytic solution pressure of the metal M." Since $e = 0$ when $P_M = p$, the electrolytic solution pressure P_M may be regarded as equal to the osmotic pressure of the metal ions which would be just sufficient to prevent the metal electrode from dissolving or passing into the ionic form, in which case there would be no development of a potential difference at the metal-liquid junction due to this cause. Hence the numerical value of P_M for a given metal and solvent may be considered as a measure of the tendency for the metal to dissolve in the solvent, i.e., to pass from the metallic to the ionic form. Thus the alkali and alkali-earth metals, which pass readily into the form of ions, have a very high electrolytic solution pressure, while the noble metals like gold, silver and platinum have a very low solution pressure. From this point of view the electrolytic solution pressure of a metal may be taken as a measure of its place in the electrochemical series. The only method thus far proposed for obtaining the value of P_M is by computation from Nernst's formula for electrode potentials given above. The value to be assigned to e depends upon the experimental determination of the "absolute" difference in potential (*see next paragraph*) between the electrode and the solution with which it is in contact. At present there is some question as to whether the actual difference of potential between the electrode and solution may not be partially due to the phenomenon of selective absorption of the ions, which is not taken into account in the above formula. For this reason the values of P_M frequently computed from the measured electrode potentials are open to question. See Le Blanc's *Lehrbuch der Elektrochemie, pages 230–235;* Lehfeld, *Phil. Mag. 48, 430, 1899.*

Absolute Electrode Potentials. — On the assumptions that the potential difference between a metal and a solution is zero when the surface tension of the metal is a maximum and that this condition is fulfilled in "dropping electrodes," or may be obtained in a properly adjusted Lippmann capillary electrometer, the absolute potential rise from the solution to the mercury in the normal calomel electrode has been found to be $e = 0.5600 + 0.0006(t - 18° \text{ C.})$ volt. It is in terms of this value for the normal calomel electrode that "absolute" electrode potentials have been expressed. On account of the uncertainty attaching to the interpretation of this value it is better for the present to adopt the arbitrary value zero as the potential drop at the calomel electrode.

[H. M. GOODWIN.]

ELECTRODYNAMOMETERS. — (*See also Ammeters; Balances, Current; Wattmeters.*) One of the most reliable and accurate laboratory instruments for current and power measurements, particularly a-c. measurements, is the electrodynamometer.

This instrument depends upon the action of one circuit carrying current upon another carrying the same current (*see Electricity and Magnetism, Principles of*). The working parts of the instrument consist of two coils, one fixed and the other movable.

SIEMENS ELECTRODYNAMOMETER. — The simplest form of electrodynamometer is that devised by Siemens, shown diagrammatically in Fig. 1. The coils are arranged at right angles to one another as shown, the heavy lines representing the fixed coil and the light lines representing the movable coil. The force of attraction or repulsion is proportional to the current in the fixed coil times the current in the moving coil, and consequently if the same current flows in the two coils, the deflection is proportional to the *square* of the current. This force is balanced by the torsion of a spring. By turning the torsion head at the top of the instrument the coils are kept at right angles. The torsional force is proportional to the angle D through which the head is turned; hence the current is

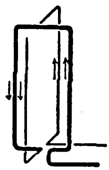

Fig. 1. Siemens Dynamometer

$$I = K\sqrt{D},$$

where K is a constant which is obtained by sending a known current through the instrument. When arranged with separate binding posts for the current or fixed coil and for the potential or swinging coil, as shown in Fig. 2, the instrument may be used as a wattmeter for either direct-current or alternating-current power measurements. The power in watts is then

$$P = K^2R_1D,$$

where K has the same value as before, and R_1 is the total resistance of the potential circuit, including the coil and external resistance R. This power includes the loss in the potential circuit, which is V^2/R_1, where V is the impressed voltage; this correction is usually small.

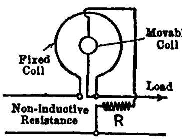

Fig. 2. Dynamometer Wattmeter

Uses of Siemens Electrodynamometer. — The instrument may be calibrated on direct current and may be used to measure either direct or alternating current or power, since when properly designed its readings are independent of frequency and wave form. High-grade standard wattmeters suitable for the precise calibration of commercial indicating wattmeter or watt-hour meters on alternating current and non-unity power-factor circuits are made on the electrodynamometer principle (*see Wattmeters*).

Design of Siemens Electrodynamometer. — The movable coil is usually suspended by a silk thread. Attached to the coil, at the point of suspension, is a spiral spring, the other end of which is attached to a movable collar. This collar carries a pointer which moves over a scale and denotes the angle of torsion of the spring. A second pointer is rigidly attached to the movable coil and registers with a fixed mark on the scale, when the fixed and movable coils are at right angles. The current is led in and out of the movable coil through mercury cups.

Dynamometers and wattmeters for use with alternating current should have as little metal used in their construction as is practical, as eddy currents will be set up in the metal parts that will influence the coil system and change the con-

stant of the instrument. The case and supporting frames should therefore be of insulating material.

Range of Siemens Electrodynamometer. — Commercial instruments of this type for measuring currents are not suitable for measuring currents of less than 0.02 ampere. Precision wattmeters (q.v.) built on the same principle may be used to measure power of the order of 1,000,000 watts on unity power factor.

Sources of Error. — The interaction of the earth's magnetic field and the current in the movable coil may be appreciable when the instrument is used for direct-current measurement unless the movable coil is perpendicular to the earth's field. This action may be detected by sending a direct current through the *movable coil only;* any deflection will be due to the earth's field.

When the instrument is used to measure alternating currents the earth's field has no effect. However, eddy currents induced in the various parts of the windings or case, or in neighboring conductors, may produce a disturbing influence. This may be tested by sending an alternating current through the *movable coil only,* the other coil being open; any deflection will be due to eddy currents. The "zero" position of the pointer should also be such that there is no mutual induction between the two coils when in the "zero" position. This can be tested by short-circuiting one coil and sending an alternating current through the other; any deflection will be due to mutual induction.

The instrument can be used for measuring the power input to circuits of low power factor only when the self induction of each coil and of the external so-called "non-inductive" resistance (*see Fig. 2*) is negligible (*see Fleming, Handbook of the Electrical Laboratory and Testing Room*).

Degree of Precision. — When properly calibrated and properly used the readings of a good Siemens electrodynamometer may be relied upon as accurate to within 1/10 per cent for a full-scale deflection. The smaller the deflection the less the percentage accuracy.

Rowland Electrodynamometer. — This instrument is identical in principle with a Siemens electrodynamometer, except that instead of noting the angle through which a torsion head must be turned, the moving coil is allowed to deflect and the deflection is noted by means of a telescope and scale. Its chief application is for measuring small alternating currents and small amounts of power in alternating-current circuits. It is seldom used except in special investigations requiring a high degree of precision or for the measurement of alternating quantities of small magnitude; e.g., alternating currents of the order of 0.1 ampere or power of from 0.01 to 1 watt. Its uses are fully described in Rowland's "Physical Papers," Johns Hopkins Press, Baltimore, 1902.

COSTS. — A simple Siemens electrodynamometer suitable for measuring currents of from 0.025 to 5 amperes costs about $75. A Rowland electrodynamometer with shunt box costs about $450.

[H. PENDER AND H. R. RANKEN.]

ELECTROLYSIS OF GROUNDED STRUCTURES. — (*See also Electrochemical Processes Industrial; Electrochemistry, Principles of.*) The following discussion will be limited to the electrolysis of grounded structures, that is, to the corrosion of metal work in the earth, due to the action of stray, vagabond or leakage currents from the grounded rails of electric railroads.

MINIMUM VOLTAGE TO PRODUCE ELECTROLYSIS. — The conduction of current through moist ground is almost entirely electrolytic, ordinary or metallic conduction being almost, if not entirely, negligible. Electrolytic corrosion occurs whenever current flows from metal into the ground, regardless of whatever difference of potential may exist between different parts of the circuit. In order that current may flow, however, it is in general necessary that the difference of potential between anode and cathode exceeds the algebraic sum of the e.m.f.'s of combination and separation of the compounds involved in the electrolytic process. An iron anode in a soil containing iron salts in solution will be attacked when the e.m.f. is infinitesimal. Where hydrogen is liberated, polarization occurs and it is the p.d. between cathode (the metal where the current leaves the ground) and ground that determines the danger of the anode (the metal at which the current enters the ground) being corroded.

CORROSIVE EFFICIENCY AND PASSIVITY. — When an electric current is passed through an electrolyte, the mass of the anode dissolved may be calculated theoretically by Faraday's law (*see index*). In practice this amount may be exceeded, or the reverse. The term "anode efficiency" or "corrosive efficiency" is used to designate the ratio of the actual to the theoretical mass of the anode dissolved. The corrosive efficiency is usually less than 100 per cent owing to the occurrence of secondary reactions. Thus the corrosion of iron, which primarily occurs by the formation of ferrous salts, should theoretically occur at the rate of 1.045 grams per ampere-hour. Owing, however, to the production of ferric salts as well, the corrosive efficiency is usually lower than 50 per cent, especially with weak currents. Under certain conditions corrosion does not take place at all; this is spoken of as a condition of "passivity." Passivity is usually due to the formation of a film of insoluble oxide or other substance, but sometimes to more complex causes.

ALTERNATING-CURRENT ELECTROLYSIS. — (*J. L. R. Hayden, Trans. A.I.E.E., Vol. 26, p. 221.*) Alternating-current electrolysis is not a phenomenon like direct-current electrolysis, on which definite quantitative general laws can be formulated, but is of the character of a secondary effect, that is, the action of the positive half-wave is not quite reversed by the action of the negative half-wave, leaving a small difference rarely exceeding one-half per cent of the electrolytic action of an equal direct current.

Alternating-current electrolysis, when expressed quantitatively, or in per cent of the action of an equal direct current, varies very greatly with the chemical character of the electrolyte. Nitrates tend to increase electrolytic corrosion; carbonates and, in general, alkalis of the soil decrease it. In general, lead is attacked more than iron.

Alternating-current electrolysis, under conditions representing as nearly as seems feasible the conditions of lead cables in the soil, does not appreciably depend upon the current density, but is practically independent thereof, except indirectly, in that very high current densities may, by an increase of temperature, give an increased corrosion.

In general, electrolytic corrosion by alternating current increases with decrease of frequency. This increase with decrease of frequency does not follow a general law, but depends largely upon the chemical character of the electro-

lyte. In general, ammonium salts and nitrates seem to give a very great increase of electrolytic corrosion with decreasing frequency, while carbonates and soils with alkaline reaction, as containing cement, may give little or no increase of corrosion with decreasing frequency.

A direct current of 1.5 per cent of the alternating current gives practically complete protection against the electrolytic action of the alternating current.

DISTRIBUTION OF EARTH CURRENTS. — The distribution of stray currents in the earth depends not only upon the resistance of the earth but also the resistance and distribution of the conducting structures in the earth.

Earth Resistance. — As the earth conducts electrolytically, its specific resistance can be calculated from the concentration of the salt solutions it contains. Such calculations are, however, generally useless, as, even with moderate specific conductance, the extent of the current path in the earth is so great that its resistance is very low, except near the electrodes. The effect of the electrodes is to concentrate the current streams into limited areas, thereby increasing the effective resistance of the earth. It is, therefore, obvious that the resistance of the earth depends more upon the electrode area than anything else.

The resistance of the earth is low when the electrodes consist of considerable lengths of track rails. This is particularly noticeable in the case of single phase lines, due to the skin effect and inductance of the rails. Thus J. Dalziel and J. Sayers (*Inst. Civil Engineers, London, 1909*) found that, on the Midland Railway, the current did not continue along the rails for any considerable length, but within a few hundred yards of the car sank gradually into the earth to re-enter the ballast at a very short distance from the power station. H. F. Parshall found that on a line eight miles long, the earth-return current was 60 per cent of the total. Probably the most exact data of this kind are those due to A. W. Copley (*Trans. A.I.E.E., 1908, Vol. 27, p. 1171*), who stated that on the New York, New Haven & Hartford Railroad the percentage of current in the earth is 25 per cent on the four-track sections and 60 per cent on the single-track sections.

This condition is not confined to single-phase systems; Claude (*L'Eclairage Electrique, p. 141, Vol. 24, 1900*) found that in complicated direct-current networks the stray current was from 25 per cent to 30 per cent of the total.

Electrolytic Zone. — When a drop of potential occurs in a track rail, the current spreads out from it into the soil in much the same way that the leakage lines of magnetic force from a long electromagnet spread out into the air; that is, almost the entire leakage current is confined to a limited zone of the earth, the extent of this zone depending upon the potential drop in the rails themselves. The stream lines of the current will tend to crowd into a pipe or cable sheath (on account of their low resistance) if these conductors are within this zone, but this tendency rapidly diminishes as the distance between these conductors and the rails increases. Compare with the tendency of an iron bar to become magnetized when placed in the leakage field of an electromagnet; the induced magnetization rapidly diminishes as the distance of the bar from the magnet is increased. Conductors at a comparatively short distance from the rails are, therefore, not liable to electrolysis unless the difference of potential between them and the rails is large or the leakage path of the current from the rails to the conductors is of low resistance. Thus in England, where the drop in the grounded return is limited to a total of seven volts, Messrs. Cunliffe found experimentally that the electrolytic zone is confined to within three feet of the track.

Potential Readings. — Random readings between rails and pipes give no definite information about electrolytic conditions. As a matter of fact, a difference of potential between a pipe and rail at any point is often greater the less

the stray currents at that point. To illustrate this, we may assume a pipe to be outside the electrolytic zone and, therefore, safe from electrolytic corrosion. If, at any point, the rail is at the same potential as the pipe, the potential of the rail at every other point will differ from the pipe. Also, if the part of the rail which is at the potential of the pipe happens to be at some distance from the power station, the pipe will be positive to the rail at all points between the earthed point and the power station. Hence the fact that the pipe is positive to the rail does not indicate that it is subject to electrolysis. A more important illustration is the case of a pipe carrying little current itself but connected to some distant pipe which *is* carrying considerable current. In such a case, a pipe may be highly electropositive to the rails and yet be quite innocent of electrolytic tendencies. These illustrations are merely specific cases of the general principle that *potential readings are useless unless taken with reference to the resistance of the earth between rails and conductors, which in turn depends upon the direction and distribution of the current stream lines.* As most electrolytic surveys made in the past consisted of potential readings taken without respect to the direction of the current flow, they gave no indication of the earth currents and afforded no criterion of electrolytic conditions.

The equipotential surfaces in the earth are, of course, perpendicular at all points to the current stream lines. If the earth currents were steady, it would be possible to determine their direction and distribution by testing for equipotential points in the earth and plotting current stream lines therefrom. Unfortunately in most practical cases the equipotential surfaces are in constant motion owing to the fluctuations of current in the track rails.

The inevitable conclusions are, that random potential readings between track rails and pipes, etc., in the earth, cannot be of any use, and that it is generally impossible to plot the current stream lines.

STRUCTURES AFFECTED BY CORROSION.—Stray currents can set up corrosion of the rails, rail spikes, cross-bonds, steel columns, etc., through which they escape into the earth, and they can set up corrosion of gas and water pipes, cable sheaths, building structures, etc., which they may enter and leave in their course through the earth. The protection of the former class of materials is entirely the concern of the railroad company which originates the earth currents; not so with the latter class, which is often of great concern to the municipalities or public-service corporations which own them. Electrolytic surveys should, therefore, be made with a clear understanding of which class of property is under suspicion of danger. As a rule, electrolysis is most destructive to the grounded metal of the railroads; foreign pipes, cable sheaths, etc., being affected in comparatively rare instances. Of all properties foreign to the railroads, the thin sheaths of telephone cables are most susceptible to electrolytic corrosion.

Measurement of Leakage Current in Grounded Return System.—The columns and foundations of elevated structures and subways, rail spikes, bare negative cables and bonds are the parts most likely to be attacked electrolytically.

In the case of the elevated railways of New York City, after about nine years' operation with the steel structure a part of the return system, it was found necessary to remove all metallic connections in the Borough of Manhattan between the track rails and structure and to install negative feeder cables to compensate for the conductivity thereby sacrificed.

The corrosion of rail spikes, while happily rare, is a matter of such grave concern to the railroads and public that it should be carefully watched for. It occurs when ties are old and water-logged or when improperly treated with preservative. Timber is ordinarily classed with the non-conductors, because,

when dry and well-seasoned, it has a high dielectric strength and practically infinite resistance. When green or moist, however, it becomes an electric conductor of comparatively low resistance. The resistance along the grain is much less than across it, and porous woods, such as oak, are better conductors than the non-porous woods such as pine. The conductivity of wood is due primarily to the presence in its pores of electrolytes formed from the salts found in natural timber, from preservatives and from salts originating from coal fumes or ashes. The flow of current, from the rails and spikes into the ties, fills the pores of the wood with iron salts, which add to the electrolytic conductivity and permit the leakage of more current. The effect is, therefore, cumulative, the leakage current increasing until the pores of the wood are completely saturated with electrolyte. Cases have been known where spikes were pitted more than half way through and where the rail flanges were badly corroded. Ties creosoted by the hollow-cell process, which leaves the fibers empty, are particularly likely to acquire high electrolytic conductivity. Red oak treated with zinc chloride is also a bad tie from the electrolytic point of view.

Columns of elevated railroads, subways, passenger stations, etc., are best tested for electrolytic trouble by means of a sensitive galvanometer used in the following way. Iron clamps with pointed tips are fastened to the column at points four or five feet apart, care being taken that the points penetrate the paint and make metallic contact with the steel. Wires are run from these clamps to a galvanometer and the deflection noted. The galvanometer having been calibrated, this gives the drop of potential in the column. The cross-sectional area of the column being known, its resistance may be calculated from the known resistivity of steel (usually 11 times that of copper). The potential drop, divided by the resistance, gives the flow of current in the column. Knowing the direction of flow, its amount and the efficiency of corrosion, the actual damage being done by electrolysis may be calculated as a definite weight of metal per annum. This method is being pursued with great success on the Electric Zone of the New York Central Railroad, the galvanometer employed being a Queen & Co's E-8010 with tube E-8011, a calibration resistance and a tripod. A deflection of one scale division is equivalent to about 0.000003 volt. Considering an average column with a resistance of 0.000,004 ohm for a 4-foot length, a deflection of one scale division corresponds to three-fourths of an ampere. Where the columns are to be encased in concrete, permanent testing terminals should be provided, preferably in the form of small iron pipes screwed into the steel and ending flush with the concrete.

Measurement of Leakage Current in Pipes, Cable Sheaths, etc.—It is not uncommon to find potential readings taken between different systems of pipes, without regard to the location of the connections, the results being recorded as differences of potential between those systems of pipes. The potential of a pipe system, however, may vary from point to point, and consequently such readings have no significance unless the points between which the potential difference is measured are specified. The significance of potential readings between specific points is that they afford an indication of the potential gradient normal to the tracks and thereby help to determine the electrolytic zone.

Making use of all possible connections to the pipe, the potential difference between these points and the anode end of the grounded system should be determined as described below and the limits of the "electrolytic zone" ascertained by noting where the potential gradient in the pipe becomes negligible. For this purpose, water hydrants and water pipes constitute the best connection points.

Potential readings between points on the same pipe line or cable sheath are sometimes made the basis of potential curves showing the drop in the pipe or

sheath. Such potential curves may be very significant when taken from cable sheaths, but are of little use for pipes on account of the variable joint resistance of the latter. Thus in case of a cable sheath of uniform resistance along the entire length tested, where the potential curve is flat, the sheath carries no current; when it is a straight sloping line, the sheath carries current without giving current to or taking current from the earth; where it changes its slope, current is either entering or leaving the sheath.

Hering's Method. — The current in a pipe may also be measured by the following method. (*C. Hering, Trans. A.I.E.E., June, 1912.*) The fundamental principle is as follows. Let P, Fig. 1, be a part of an underground pipe which has been uncovered and through which an unknown current I is flowing. Let D be a sensitive galvanometer, millivoltmeter or any other suitable form of detector; there should preferably be no variable resistance like an unbonded pipe joint between the two contact points. Let A be an ammeter, B a few battery cells and R an adjustable resistance; the shunt circuit containing them is connected as shown, anywhere outside of the points of application of the voltage detector, the farther away the better; they may even be on the other side of a joint.

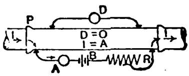

Fig. 1

To find the current flowing in the pipe adjust the resistance R until D reads zero; then the current due to the battery B will be exactly equal and opposite to the current in the pipe. Hence the reading of the ammeter A gives the current in the pipe.

If D is a galvanometer with proportionate deflections, instead of a mere detector, then by taking a deflection immediately after the shunt circuit has been opened a reading proportionate to the drop of voltage for that current will be obtained. The instrument D is thereby calibrated to read the pipe currents directly and can be used for this purpose thereafter; the test with the battery current is therefore merely of the nature of a preliminary calibration, and need be carried out only once for each station.

Instead of attempting to adjust the current in the shunt to bring the voltage D to zero, it is often more convenient to use a regular measuring instrument for D instead of a mere zero detector, and to pass a definite current through the shunt, say 10, 50 or 100 amperes, reading the two deflections of D when this current is on and when it is off; this had best be repeated several times. The difference between these two readings then corresponds to the current in the pipe. The best current to use is that which will reduce the original deflection as much as possible. By thus using the difference between a large and a small deflection the errors due to a loose zero, which are so common with highly sensitive instruments, are reduced.

Methods for overcoming fluctuating currents are given by Hering in the paper cited above.

Having thus calibrated the voltmeter V at each of two neighboring stations, the currents which enter or leave the pipe between them may be determined, with the fluctuating currents, by taking the readings of the two instruments simultaneously by means of visual or telephonic signals, preferably at times when the currents are momentarily steady.

Measurement of Current Leaving Pipe at Any Point. — The strength of the current at the point where it is leaving the sheath may be determined by the following test, which involves the use of a temporary bond in the form of a stout copper cable, electrically connected through an ammeter with both sheath and rail. Let

V = total drop of potential in the rails from *their* anodic center to the point where the temporary bond is connected.

By "anodic center of the rails" is meant the center of gravity of the leakage current *leaving* the rails.

v = difference of potential between the sheath and rail at the bonding point prior to the insertion of the bond.

v_1 = same, after the insertion of a bond which carries I amperes. The current in the bond is read from the ammeter.

Then the earth current, i, after the insertion of the bond will be

$$i = I \cdot \frac{k}{1-k},$$

where

$$k = \frac{v_1}{v} \cdot \frac{V-v}{V-v_1}.$$

The earth current from the pipe, without bonding, would be

$$\frac{V-v}{V-v_1}(I+i).$$

For example, suppose the total drop in the rails to be 100 volts and the differences of potential between the pipe and the rails at the bonding point to be five volts before the bond is inserted, and one volt after. Suppose the current in the bond is found to be 50 amperes.

Then

$$V = 100. \qquad v = 5. \qquad v_1 = 1. \qquad I = 50.$$

$$k = \frac{1}{5} \cdot \frac{100-5}{100-1} = 0.19.$$

$$i = 50 \cdot \frac{0.19}{1-0.19} = 12 \text{ amperes, approximately.}$$

Without bonding, the current would be

$$= \frac{100-5}{100-1}(50+12) = 59 \text{ amperes approximately.}$$

The above formula is based upon the following assumptions:

(1) That the drop in the rails V is not affected by the insertion of the bond.

(2) That the area over which the current from the pipe or sheath enters the earth is short. For proof of formula, see *Elect. World, 1910, Vol. 55, p. 407.*

PREVENTION OF ELECTROLYSIS. — Electrolysis may be partially or wholly prevented by the use of bonds, concrete coverings, paint, tape or braid, or by employing boosters, or by insulating the return circuits.

Protection from Electrolysis by Bonding. — Bonds are not only useful for testing purposes; they may be applied permanently to reduce the earth currents. There are certain effects, however, which may render their use inadvisable.

1. If one piping system is connected to the rails or bus, a difference of potential will be established between it and all other underground metallic structures and it will, therefore, attract current from the latter and expose them to electrolytic danger. A bonded piping system thus becomes a part of the trolley return circuit and the owner may become a party to whatever damage may occur in the others.

2. A considerable current in a gas pipe is a serious fire hazard and in a lead cable sheath is a menace to continuity of service.

3. Electrolysis is promoted at all imperfect joints and connections.

In spite of these objections bonds are very largely used to protect cable sheaths from corrosion. To be most effective, the sheath should be connected to the negative bus by an insulated cable and the bus itself should be connected to the track rails by insulated cables only.

Protection of Steel by Concrete.—The conductivity of concrete depends upon its porosity and wetness. Tests have shown that when wet the specific resistance may be as low as 20 or 30 ohms per yard cube and when dry, as great as 2000 ohms. The extent to which concrete prevents corrosion depends upon its chemical composition and porosity. Some cement protects iron by forming a protective coating of silicate of iron (*E. Noillion, Proc. Inst. Mech. Eng., 1905, p. 485*). The corrosive efficiency of steel in concrete is extremely variable, depending largely upon the nature of the electrolyte with which the concrete is impregnated, and upon the applied e.m.f., being much less with low than with high electromotive forces. For example, a reduction of e.m.f. to one quarter may reduce the corrosive efficiency to one half of one per cent of its former value. This subject is being investigated very thoroughly by the Bureau of Standards. The following tests show values of corrosive efficiency for unpainted iron obtained by some experimenters.

Nature of electrolyte	Thickness concrete protection, inches	Amperes per sq. in. of anode	Volts anode to cathode	Corrosive efficiency, per cent	Time of test, days	Name of experimenter
Lake water...	4	Variable	8	1.05 to 6.88	180	C. F. Burgess
3 per cent salt solution....	2	Variable	8	40 to 80	64	C. F. Burgess
Fresh water..	3½	0.00164	Variable	Over 60	30	A. A. Knudson
Salt (sea).....	3½	0.00164	Variable	Over 41	30	A. A. Knudson
Salt (sea).....	..	..	..	Average 33	..	G. Schaffer

Below 50°C. the efficiency of corrosion is very small, but above that temperature, rises rapidly. Increasing the current density does not materially change the corrosive efficiency at any given temperature. If the heating effect of the current is sufficient to raise the temperature to 50°C. (= 122°F.), or more, active corrosion begins. Below 50°C., the iron remains passive or nearly so, provided that there are present no foreign ingredients of marked corrosive tendencies, such as salt or calcium chloride. The addition of 0.33 per cent by weight of calcium chloride increased the efficiency of corrosion from practically zero to 80 per cent.

The exact cause of passivity at ordinary temperatures is not fully understood, but it is at least partially due to the concentration of calcium hydrate near the cathode surface by the current, where it comes in contact with the carbon dioxide absorbed by the water from the air, with resulting precipitation of calcium carbonate which fills the pores of the concrete, interposing a high resistance.

Briefly stated, concrete affords some protection to steel work, but, in every suspected case, determination should be made of the current flow and corrosive efficiency.

Salt should never be used in concrete if there is the slightest probability of action by electric currents, since the addition of even a fraction of one per cent of chlorine is sufficient to increase the rate of corrosion a hundred fold.

Destruction of Concrete by Electrolysis. — Some experimenters have found that where iron imbedded in concrete becomes an anode, not only is the iron corroded but the concrete also is cracked. This action is due to the internal stress set up by the increase of volume which the iron suffers when it changes to an oxide or salt. The current has no direct effect upon the concrete at the anode even when sufficiently strong to liberate chlorine from the brine used to impregnate it. (*C. E. Magnusson, Trans. A.I.E.E., June 1911*). At the cathode, however, the concrete becomes softened and loses its bond with the electrode. See papers by E. B. Rosa, B. McCallum & A. S. Peters, *Nat. Assn. of Cement Users*, 1912, and abstracted in *Eng. News*, 1912, Vol. 68, p. 1162. No action, however, occurs on concrete through which current flows, except at the electrodes.

Protection of Steel by Paint. — Experiments by M. Toch, C. E. Magnusson, G. H. Smith and others have shown that unpainted steel imbedded in concrete can be electrolytically corroded at the anode, but that a good insulating paint applied to the steel prevents such corrosion. Acid-proof paints with tar or asphalt base such as are commonly used to protect steel imbedded in concrete are usually effective. A typical paint of this kind has the following composition: 16 parts coal-tar paint, 4 parts Portland cement, 3 parts kerosene.

When the p.d. between cathode and ground does not exceed 5 volts the corrosive efficiency of an anode, so protected, is usually less than 1 per cent.

Protection of Sheaths by Tape or Braid. — H. W. Fisher found that electrolysis is not prevented by covering the lead with a weatherproof tape or braid saturated with insulating compound. With such coverings the electrolytic action is apt to be concentrated in spots and thus eat through the lead more quickly. For the same reason, lead-covered cables, laid in wooden boxes filled with pitch or bitumen, deteriorate rapidly under electrolytic action.

The Laclede Gas Company of St. Louis (*Elect. World, 1911, Vol. 57, p. 1103*), however, have had favorable experience with tape protection. Their wrought-iron pipe, in sizes from 3 to ¾ inch, was coated with a tar and pitch mixture, heated and thinned sufficiently to flow easily, and onto this a 4-inch paper ribbon was wrapped spirally, its edges overlapping. This paper covering was then tar painted and again wrapped with paper, the process being repeated until four successive coats were applied. Pieces of pipe thus insulated were placed in the ground under the most distinctive conditions of electrolysis, along with other lengths not so treated. After being taken up at the end of two years the unprotected pipes were badly pitted and almost consumed, while the insulated piping was practically the same as when laid. Although no test has yet been made carrying the insulated pipe to total disintegration, it is believed that pipe so treated will have its life at least doubled, and if this is true an expenditure for insulation equal to that of the cost of the bare pipe is justified. Only service runs are being so treated, the cast-iron mains being less subject to corrosion and electrolysis than the service pipes. The tar and paper coating is very hard when cooled, and the pipe lengths need to be handled with no more care than bare pipe (*J. L. Fitzhugh*).

Protection by Booster. — It is often proposed to render grounded metal work electronegative to the rail return by means of a booster, but such proposals are seldom carried into execution on account of the expense they involve. Thus L. B. Stillwell (*Trans. A.I.E.E., 1907, Vol. 26, Part 1, p. 265*) said: "The plans of the Hudson Company contemplate the use of a booster to prevent possible electrolytic damage to the metallic shells of the tube tunnels destined to connect the Borough of Manhattan and the Jersey Shore. The Interborough Rapid Transit Company is also proposing to use them for a similar purpose in connection with the tubes under the East River." It was, however,

A scheme recently adopted with success at Karlsruhe, Germany, involves the use of a booster which does not have to carry the main current and which is therefore comparatively small. At places where there is danger for gas pipes or water pipes, electrodes are placed in the earth in the neighborhood of the pipes and these electrodes are connected to the positive pole of a low-voltage generator or storage battery, while the pipe to be protected is itself connected with the negative pole. In this way electric current is forced to enter the pipe from the earth so that anodic destruction of the pipe is impossible. The power consumption is said to be insignificant. (*Geppert & Liese, Elek. Kraftb. u. Bahnen, Feb. 14, 1912.*)

Boosters are used to prevent the pitting of condenser tubes, especially where salt water is used for cooling. An example of such an installation is in the Power Station of the Long Island railroad on the East River, New York (*Street Railway Journal, 1906, Vol. 27, p. 545*).

Protection by Insulated Returns. — The only certain way of eliminating all electrolytic trouble is by limiting the drop of potential in the grounded conductors to a moderate amount, as is done in Great Britain by the Board of Trade. This can be most economically effected by the use of insulated negative feeder cables tapped into the rails at intervals, as described under Distribution, and by G. I. Rhodes (*Transactions of the A.I.E.E., 1907, Vol. 26, Part 1, p. 247–263*). Such a system is equivalent to a large number of substations, as far as its effect upon the potential drop in the rails is concerned. The maintenance of efficient bonding is a most important factor in limiting the drop of potential in rails and, therefore, in preventing electrolysis.

BIBLIOGRAPHY. — A complete bibliography of the subject up to 1908 is given in a paper by W. H. Gee, *Electrolytic Corrosion, Jour. Inst. El. Eng., 1908, Vol. 41, p. 425*. In addition to these references and those given in the text, the following more recent papers should be consulted: Burgess, C. F., *Electrolytic Corrosion of Iron in Concrete, West. Soc. Eng., 1911, and Elec. World, 1911, Vol. 57, p. 827;* Chapman, C. M., *The Effect of Electrolysis on Metal Imbedded in Concrete, Eng. Cont., 1911, Vol. 35, p. 99;* Cunliffe, J. G., and M. [W. A. Del Mar.]

ELECTROMAGNET WINDINGS. — (*See also Electricity and Magnetism, Principles of; Electromagnets, Lifting and Plunger; Generators; Motors; Transformers.*) Any coil or winding carrying an electric current forms an electromagnet; the term electromagnet is also generally used for such a coil, particularly when it has a magnetic core, whether it is actually carrying a current or not. The winding of most electromagnets is in the form of a cylindrical helix of one or more layers; such a winding is called a solenoid. This winding is usually built up on a bobbin, which may be fixed rigidly to a magnetic core, or the core or part of it may be movable, in which case the electromagnet is called a plunger electromagnet. The electromagnet may also be built upon a horseshoe shaped core, with a movable yoke or "armature" which is attracted to the core when a current is established in the winding. See *Electromagnets, Lifting and Plunger*.

DESIGN AND CONSTRUCTION OF WINDINGS — The problem is to construct a coil which, for a given voltage across its terminals, will produce a given number of ampere-turns, and which will not overheat. Usually one or more of the dimensions of the coil are also fixed by the conditions under which the coil is to be used. The following factors must be taken into account in designing a winding:

Insulation from Core; Design of Bobbin. — When the core is fixed, two washers of hard rubber or vulcanized fiber are forced on at either end of the core. The core is then insulated with a wrapping of paper, mica or oiled linen, and is then ready to be wound. When the core is movable, the two end washers are forced on to the ends of a brass tube or a tube made of the same material as the washers. When a metallic tube is used the washers are sometimes made of the same metal. In the case of a quick-acting plunger magnet a metallic bobbin, if used, should be slotted, in order to avoid eddy currents; this also applies to all forms of alternating-current electromagnets.

Insulation of Wires; Insulation Between Layers; Baking. — The wire may be insulated with a cotton, silk or asbestos wind or by a coating of enamel. In high-voltage solenoids the various layers of wire are insulated from each other by paper, mica or oiled linen wrappings, or the entire winding is divided into several sections separated by vertical washers of insulating material. The wound coil may be further insulated by dipping it into an insulating varnish in a vacuum or at atmospheric pressure, after which it is either air-dried or baked.

Aluminum wires and ribbons are used extensively by some manufacturers, especially abroad. In this case the layer of oxide on the wire is the only insulation which is used, but inasmuch as this insulation cannot be destroyed by heat, the coils can be run at much higher temperatures, which is of special value for lifting magnets and similar devices. The oxide layer will stand a potential stress of about 0.5 volt. See article on *Use of Naked Aluminum Wire in Electromagnets*, by H. F. Stratton, Elec. Wld., 1912, Vol. 60, p. 400.

Temperature Rise of Winding; Watts per Square Inch. — The rise of temperature of the winding will depend primarily upon the average rate at which heat is developed by the electric current and the amount of exposed surface from which this heat can be radiated; the temperature rise will also depend upon the depth of winding, the circulation of the air, etc. The hottest spot in the winding should never reach a higher temperature than 90° C. When the interior of the winding is at 90° C. the temperature of the external surface, as measured by a thermometer, will usually be much less, as will also the average temperature measured by the change of resistance method.

As a rough approximation a solenoid winding should be so designed that the average power developed will not exceed 0.5 watt per square inch of radiating surface for an open winding, and will not exceed 0.7 watt per square inch of radiating surface for an iron-clad solenoid. In figuring the radiating surface of an open winding, the surface of the hole through the solenoid is not included, and the end surfaces are included only when the solenoid is short. By the radiating surface in the case of an iron-clad solenoid is meant the surface of the winding which is in contact with the iron. A radiation of 0.5 watt per square inch and 0.7 watt per square inch for an open and an iron-clad winding respectively corresponds roughly to an average temperature rise of approximately 60° C.; for other rates of radiation the temperature rise will be approximately proportional to the watts per square inch radiated.

For short-time service, i.e., when the solenoid is energized only for short intervals with long intervals between the applications of power, the thermal capacity of the solenoid will permit of a greater dissipation of energy in the winding without overheating it.

Space Factors; Round Versus Square Wire; Layer Versus Haphazard Windings. — By the space factor of a winding is meant the ratio of the space occupied by the conductors to the total space occupied by the conductors, the insulation on the conductors and the voids between conductors. The space factor for strips and square wires is greater than for round wires, but strip and square wires are not extensively used in small sizes because of the increased amount of insulation required for a given section of conductor, and because of the tendency of such wires to twist in winding so that they lie upon their corners instead of upon their faces. However, for conductors of larger section than No. 10 B. & S. gauge, square wire is often used.

In winding wires larger than No. 18 B. & S. it always pays to wind them carefully in smooth layers ("layer" wound), but for smaller sizes used for open solenoids (as distinguished from iron-clad solenoids) the gain in space factor does not as a rule warrant this care and the wires are wound in a more or less haphazard fashion ("haphazard" wound). For iron-clad solenoids, however, a layer winding is always used, for economy of material requires that the winding space be kept as small as possible. The dotted curves A and B in Fig. 1 for haphazard windings are taken from an article by F. A. Willard (*Elec. Wld.*, *1906, Vol. 47, p. 823*).

Round wires are sometimes so wound that the wires of one layer lie in the hollows between the wires of the layer underneath; the wires in this case are said to be embedded. Objections to this procedure, however, are that each layer must be started from the same end and the insulation on the wires becomes tightly compressed and therefore is less effective; in most instances the extra labor and the diminution of insulating quality offset the small gain in space factor, which seldom exceeds 3 per cent.

The space factor s for a layer winding of round wire without embedding, and making no allowance for extra insulation between layers is

$$s = \frac{\pi}{4}\left(\frac{d}{d + 2t}\right)^2, \qquad (1)$$

where d is the diameter of the conductor and t the thickness of insulation. Values of s for various sizes of wire and various thickness of insulation are given by the curves in Fig. 1. The "over-all" space factor, including the allowance for the space occupied by the extra insulation, if any, between layers, is equal to the value of s from these curves multiplied by $(1 - e)$, where e is the ratio of the space occupied by this extra insulation to the total winding space.

Thickness of Insulation. — Magnet wire is usually referred to as "single covered," "double covered" and "triple covered," depending upon the number of layers of insulating threads wrapped around it. Different manufacturers

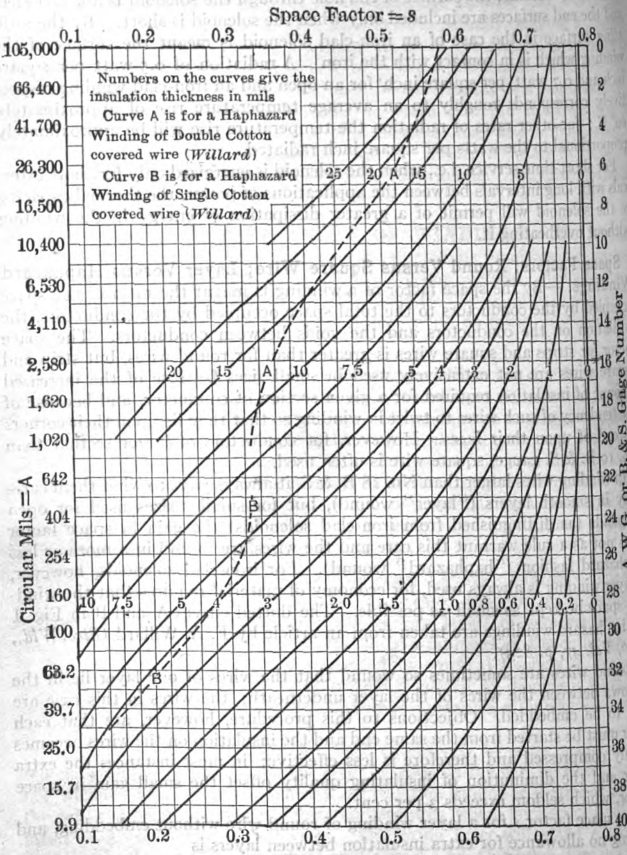

Fig. 1. Space Factor Curves

use different thicknesses for these layers, with the result that the thickness of the insulation on a "double cotton covered" wire of a given size or gauge number depends upon the manufacturer of the wire. In the following table is given the range in insulation thickness, taken from the catalogues of several large manufacturers.

INSULATION THICKNESS IN MILS

Size of wire A.W.G. or B. & S.	Single* cotton covered	Single* silk covered	Asbestos covered (Deltabeston)	Enamel covered
0000 - 00	4.5 - 7.5	....	....	....
0 - 3	4.5 - 7.5	....	18	....
4 - 7	4.5 - 7.5	....	16	....
8 - 10	4.5 - 7.5	....	14	....
11 - 12	2.5 - 5.0	....	12	....
13 - 15	2.5 - 5.0	....	10	1.5
16 - 19	2.5 - 5.0	1 - 2	10	1.1
20	2.0 - 4.0	1 - 2	10	1.1
21 - 23	2.0 - 4.0	1 - 2	....	1.0 - 1.0
24 - 28	2.0 - 4.0	1 - 2	....	0.8 - 1.1
29 - 33	2.0 - 4.0	1 - 2	....	0.7 - 1.0
34 - 36	2.0 - 4.0	1 - 2	....	0.4 - 0.7
37 - 40	2.0 - 4.0	1 - 2	....	0.3 - 0.6

* "For double covered" multiply these thicknesses by 2, and for triple covered multiply by 3.

Winding Calculations for Direct-current Solenoids. — Round solid wires are assumed throughout. Let

s = space factor, from Fig. 1.

k = ratio of specific resistance of conductor used to that of standard annealed copper at 20° C. For copper of 100 per cent conductivity at 20° C., $k = 1$; for copper of any other per cent conductivity, say C per cent, at any other temperature, say t° C.,

$$k = \frac{100}{C} + 0.004\,(t - 20).$$ See also *Wires and Cables, Bare*, and *Wires, Resistor*.

A = cross section of wire in circular mils (= square of diameter in thousandths of an inch).

$n = \frac{1{,}270{,}000\, s}{A}$ = number of conductors per square inch, the square inch being taken perpendicular to the direction in which the wire is wound.

$\rho = \frac{1{,}100{,}000\, sk}{A^2}$ = resistance of the winding per cubic inch of the winding space, excluding the space, if any, occupied by extra insulation between layers; ρ is in ohms.

$w = 0.271\, s + 0.040$ = weight of the winding (copper and cotton insulation) per cubic inch of the winding space, exclusive of the space, if any, occupied by extra insulation between layers; w is in pounds.*

E = impressed volts.

(NI) = ampere-turns, where N is the total number of turns and I the current in amperes,

* This formula also holds approximately for other kinds of insulation and for most alloy resistance wires. Calling g_c the specific gravity of the conductor and g_i the specific gravity of the insulation, the exact formula is

$$w = 0.0362\,(g_c - g_i)\, s + 0.0284\, g_i.$$

Underhill gives g_i as 1.6 for asbestos, 1.4 for cotton, and 1.0 for silk.

p = allowable watts per square inch of radiating surface (may be taken approximately as 0.5 for open and 0.7 for iron-clad solenoids, see above).

S = radiating surface, in square inches, calculated as described above under *Temperature Rise of Winding*.

l = mean length of turn in inches (see Fig. 2 for a simple solenoid).

T = depth of winding space in inches (see Fig. 2), excluding the space occupied by the extra insulation, if any, between layers.

L = length of winding space in inches (see Fig. 2).

$V = LlT$ = volume of winding space in cubic inches, excluding space occupied by the extra insulation, if any, between layers.

The problem is usually to find the size of wire and necessary winding space for a coil which will give, without overheating, a required number of ampere-turns (NI) at a given impressed voltage E. The diameter of the core or spool is also usually known, or at least must not exceed certain fairly well-defined limits, depending upon the service for which it is to be used. The procedure is then to assume a reasonable value for the mean length of turn l. The size of wire is then immediately fixed by the relation

$$A = \frac{kl\,(NI)}{1.16\,E}. \tag{2}$$

From Fig. 1 the corresponding size of wire (A. W. G. or B. & S. gage) and the corresponding space factor s may then be found.

The volume V and radiating surface S of the coil must then satisfy the relation

$$\frac{LTS}{l} = \frac{k\,(NI)^2}{1{,}470{,}000\,ps}. \tag{3}$$

The length L and depth T of the winding space must be so chosen that this relation will be satisfied; as a rule this can be done only by cut and try. Note that changing the depth T of the winding space will also change the mean length of turn l, unless the diameter of the core or spool is so altered as to keep l constant. The cross section of the wire varies directly as l, as shown by equation (2), and therefore the value of the space factor s to be used in (3) will depend upon l, but only to a slight extent except in the case of very small wires.

Having determined the cross section of the wire (A), the mean length of turn (l) and the dimensions (L and T) of the winding space so that both (2) and (3) are satisfied, the total number of turns in the winding will be

$$N = nLT = \frac{1{,}270{,}000\,sLT}{A}, \tag{4}$$

and the current is then equal to the given number of ampere-turns divided by N and the total length of wire is equal to Nl.

The total resistance R and total weight W (including insulation) of the wire may then be found directly from a wire table, or may be calculated from the formulas

$$R = \rho V = \frac{klN}{1.16\,A} = \frac{1{,}100{,}000\,skLTl}{A^2}, \tag{5}$$

$$W = wV = (0.271\,s + 0.040)\,LTl. \tag{6}$$

See note at bottom of preceding page regarding w.

Calculation of Open Solenoid of Circular Cross Section. — In the case of a coil wound on a spool of diameter D, see Fig. 2, the mean length of turn is $l = \pi\ (D + T)$. Assuming that the outside cylindrical surface of the winding is the only radiating surface, which is only approximately true, as pointed out above, $S = \pi\ (D + 2\ T)L$. Whence, putting

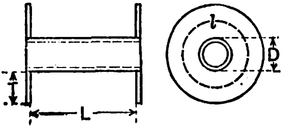

Fig. 2.

$$Q = \frac{k(NI)^2}{1{,}470{,}000\ ps}, \qquad (7)$$

the required length of coil for a given diameter of core D and depth of winding T is

$$L = \sqrt{\frac{(D + T)Q}{(D + 2\ T)T}}. \qquad (8)$$

When L is given instead of T, then the required depth of winding is

$$T = \frac{1}{4}\left[\left(\frac{Q}{L^2} - D\right) + \sqrt{\left(\frac{Q}{L^2} - D\right)^2 + \frac{8\ QD}{L^2}}\right]. \qquad (9)$$

In either case, the number of turns, total resistance, weight, etc., are found as described above for the general case.

Example. — Required to design an open solenoid 10 inches long and having an internal diameter of 1.5 inches, to give 12,000 ampere-turns at 110 volts, the heat developed not to exceed 0.5 watt per square inch of radiating surface (taken as the outside cylindrical surface of the coil). Assume a mean length of turn equal to 10 inches, then from (2) the required cross section of the wire, assuming copper at 70° C., is $A = 1130$ cir. mils. From Fig. 1 the space factor is then $s = 0.62$, assuming single cotton-covered wire with 2-mil insulation wound in layers. From (7) the value of Q is then $Q = 380$, whence from (9) the required depth of winding is $T = 2.36$ inches. The actual mean length of turn is then $l = 12.1$ inches which substituted in (2) gives for the cross section of the wire required, $A = 1368$. This wire section gives a space factor, see Fig. 1, of $s = 0.63$, which agrees practically with the value $s = 0.62$ used above. The nearest commercial size of wire is No. 19 B. & S., having a cross section of 1288 cir. mils. If this size of wire is used the actual ampere-turns will be $NI = 11{,}300$. From (4) the total number of turns will then be $N = 14{,}700$, and from (5) the total resistance will be $R = 143$ ohms. The current is then $I = 0.77$ amperes. The total weight of the winding is then from (6),

$$W = 60 \text{ pounds.}$$

BIBLIOGRAPHY. — See *Bibliography* in article on *Electromagnets, Lifting and Plunger.*

[H. PENDER AND R. G. HUDSON.]

ELECTROMAGNETS, LIFTING AND PLUNGER. — (*See also Electricity and Magnetism, Principles of; Electromagnet Windings.*) A solenoid provided with a movable magnetic core, or with a fixed core and movable "armature," serves as a very convenient means of causing an electric current to produce a direct mechanical pull. This principle is utilized in various forms of lifting magnets, relays (q.v.), contactors (*see Switches*), electric brakes, clutches, etc. In the paragraphs following are given the formulas required in calculating the pull of various kinds of electromagnets in terms of their dimensions and ampere-turns, and also a brief statement of the applications of the various types.

Approximation of Formulas; Leakage Factor. — In applying the formulas given below, it should be noted that in general the effect of magnetic leakage is neglected. The leakage factor varies so greatly with the different forms of electromagnets that it is impossible to go into this matter in detail in the limited space available for this article. The designer, in making an allowance for leakage, has to rely chiefly upon his previous experience with other magnets of the same general form and dimensions. Merely as a rough guide to the designer who has not had this experience, it may be stated that for magnets of reasonable shape and dimensions, the formulas for pull given below may be relied upon to give the actual pull with an error of less than $\pm$ 10 per cent, the actual pull usually being less than the calculated pull. Under certain conditions the agreement between the actual pull and calculated pull may be much closer than the difference just stated.

SIMPLE SOLENOID AND PLUNGER. — The simplest type of electromagnet is a simple solenoid, as shown in Fig. 1, consisting of a cylindrical coil of circular or rectangular section and an iron plunger which fits into the inside of this coil. When current passes through the coil the plunger is attracted.

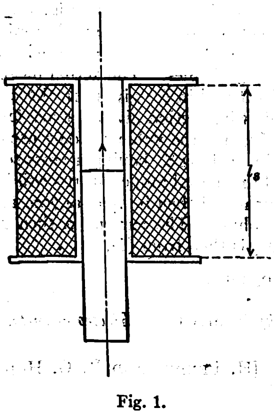

Fig. 1.

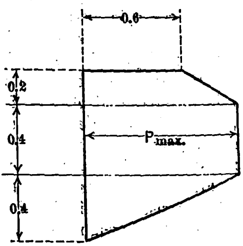

Fig. 2.

Variation of Pull of Simple Solenoid During the Stroke. — The pull of the simple solenoid varies between approximately zero when the plunger is at the lower end of the coil and a maximum which is nearly constant over approximately 40 per cent of the length of the coil. The maximum is reached when the plunger has entered the coil a distance of approximately 40 per cent. When the plunger has entered the coil 80 per cent of its length, the pull de-

creases again, reaching a value of about 0.6 of the maximum pull when the plunger is even with the top of the coil. The approximate pull variation is shown in the diagram, Fig. 2; of course the actual variation is a smooth curve, such as shown by curve A in Fig. 6.

Calculation of Pull of Simple Solenoid. — The calculation of the exact pull of such a magnet is very complicated, being dependent not only upon the ampere-turns, but also upon the shape of the coil, the size and length of the plunger and the induction in same. For practical purposes the maximum pull, when the plunger is at least as long as the coil, can be represented by the formula

$$P_1 = \frac{cANI}{l_s} \qquad \text{pounds,} \qquad (1)$$

where c = the pull in pounds per square inch per ampere-turn per inch of coil length,
A = the area of the cross-section of plunger, in square inches,
I = the current in the coil, in amperes,
N = the number of turns in the coil,
l_s = the length of the coil, in inches.

It has been found by the author that c varies between 9×10^{-3} and 10.5×10^{-3}. For practical purposes sufficiently close results are obtained if c is taken equal to 10^{-2}. The formula shows that the maximum pull is directly proportional to the current, which makes this type of magnet especially suitable for relays and instruments which should be very sensitive.

The pull at any point in the stroke may then be expressed by the formula

$$P_1 = \frac{10^{-2} ANI}{l_s} \cdot k \qquad \text{pounds,} \qquad (2)$$

where k is a factor which gives the ratio of the pull at any point of the stroke to the maximum pull; Fig. 2 gives the approximate value of k at various points of the stroke.

IRON-CLAD ELECTROMAGNET WITH FLAT-END PLUNGER. — The simple solenoid is a very inefficient type of magnet, because a large percentage of the reluctance of the magnetic path is found in the long air path outside the coil. Therefore, the plunger magnet is modified by putting an iron return circuit around the outside of the coil, thus reducing considerably the reluctance of the path and increasing the work which can be obtained with a certain amount of power, and with a certain expenditure of energy in the coil. Fig. 3 shows this type of "iron-clad" magnet. In its highest position the plunger strikes against the frame, so that in reality the magnet represented is a special form of magnet with stop, which is described below. If it is desired to have the pull decrease towards the end of the stroke, a hole similar to the one on the lower end is drilled in the upper end of the frame, and the plunger permitted to protrude through it.

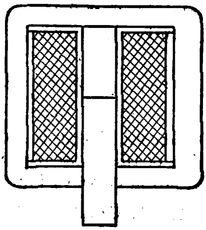

Fig. 3.

Use of Stop to Increase Pull. — The total pull on a plunger depends on the total number of flux lines which pass through it. For a given number of ampere-turns the total number of flux lines may be increased by decreasing the reluctance of the magnetic circuit. This reluctance may be still further reduced by using

a plug or stop in the upper part of the solenoid of such a length that the air-gap is central to the coil for the maximum travel which is required. This form is shown in Fig. 4.

Pull of Stop on Plunger; "Air-gap Pull." — The pull P_2 between the stop and plunger may be expressed by the formula

$$P_2 = \frac{B^2 A}{72 \times 10^6} \qquad \text{pounds,} \qquad (3)$$

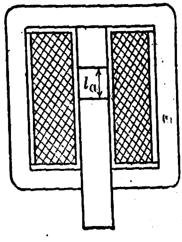

Fig. 4.

where B is the flux density in the air-gap* perpendicular to the end surface of the plunger, in lines (maxwells) per square inch, and A the area of the end of the plunger, in square inches (*see Electricity and Magnetism, Principles of*). The value of B may be calculated from the ampere-turns of the coil and the dimensions of the magnetic circuit in the same manner as the flux due to the field coils of a generator is calculated; see *Generators, Direct-current*. Or, neglecting leakage and the reluctance of the iron part of the path, B may be calculated approximately from the formula

$$B = \frac{3.19\, NI}{l_a} \qquad \text{lines per sq. in.,} \qquad (4)$$

where NI is the total ampere-turns of the coil and l_a is the length of the air-gap in inches. Combining (3) and (4) gives

$$P_2 = 1.4 \times 10^{-7} A \left(\frac{NI}{l_a}\right)^2 \qquad \text{pounds.} \qquad (5)$$

This pull of the stop on the plunger is usually referred to as the "air-gap pull." The actual variation of this air-gap pull with the length of the air-gap, for a particular magnet, is shown in curve B, Fig. 6.

Total Pull of Iron-clad Solenoid with Stop. — The total pull of the iron-clad solenoid with stop may be looked upon as due to two components, the solenoid effect P_1 given by equation (2) and the pull P_2 between stop and plunger given by equation (5); hence the total pull is

$$P = 10^{-2} A NI \left(\frac{k}{l_s} + \frac{1.4 \times 10^{-5}\, NI}{l_a^2}\right) \qquad \text{pounds.} \qquad (6)$$

When the air-gap is short and at the center of the solenoid $k = 1$. The variation of this total pull with length of air-gap for a particular electromagnet is shown in curve C, Fig. 6.

IRON-CLAD SOLENOID WITH CONED PLUNGER. — It will be noted that for a given air-gap pull P_2, the ampere-turns required are directly proportional to the length of the air-gap. If, therefore, for the same stroke the length of the path for the magnetic lines through the air-gap can be reduced, the pull for the same ampere-turns will be increased, or if the pull remains constant the ampere-turns to obtain it can be decreased. This is accomplished by

* Strictly, B in this formula is the actual air-gap flux density less the flux density which would be produced by the solenoid were there no iron whatever in its magnetic circuit. This correction, however is smaller than the probable error in calculating B and may therefore be neglected.

coning the end of the plunger, as shown in Fig. 5. For such a magnet the stroke should not be much in excess of the plunger diameter, as the leakage increases considerably with longer strokes, and this defeats the object of the coning. As the induction in the iron plunger is greater than the induction in the air-gap, there is a limit to the practicable value which may be given to the cone angle; this limit is about reached for cast iron for a cone angle of 28° and for cast steel for a cone angle of 19 degrees.

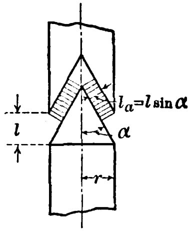

Fig. 5.

"Air-gap Pull" on Coned Plunger. — In the following it is assumed for simplicity's sake that a uniform flux at right angle to and distributed over the entire surface of the cones passes between plunger and plug. This is not strictly correct, especially for long strokes and the pull calculation is therefore only approximately correct.

Let

l = length of stroke, in inches,
A = total cross-section of plunger, in square inches, $= \pi r^2$ where r is the radius of the plunger, see Fig. 5,
α = angle of the cone, in degrees, see Fig. 5,
NI = total ampere-turns of coil.

Then the flux density in the plunger is

$$B_i = \frac{3.19\, NI}{l \sin^2 \alpha} \quad \text{lines per sq. in.} \tag{7}$$

and the air-gap pull in the direction of the stroke is

$$P_2 = 1.4 \times 10^{-7} A \left(\frac{NI}{l \sin \alpha}\right)^2 \quad \text{pounds.} \tag{8}$$

The solenoid pull, as found by experiment, is practically the same as for a flat-end plunger, equation (1). Whence the total pull on the coned plunger is

$$P = 10^{-2} ANI \left(\frac{1}{l_s} + \frac{1.4 \times 10^{-5} NI}{l^2 \sin^2 \alpha}\right) \quad \text{pounds,} \tag{9}$$

where l_s is the length of the solenoid winding assuming the gap at the center of the solenoid ($k = 1$).

Note that $l \sin \alpha = l_a$ is the "effective" length of the air-gap, i.e., the length perpendicular to the surface of the cone. Hence, comparing with equation (6), it is seen that the pull on a coned plunger for the same effective air-gap is the same as on a flat-end plunger, but the length of the stroke is increased in the ratio of $\frac{1}{\sin \alpha}$. Comparing equation (7) with equation (4), it is seen that this advantage is gained by increasing the flux density in the plunger by the square of $\frac{1}{\sin \alpha}$. For small air-gaps, therefore, the coned plunger becomes saturated much more quickly for the same current than does the flat-end plunger, and the leakage and the reluctance of the iron part of the path produces an appreciable effect, causing the pull to become almost constant for small air-gaps instead of increasing as shown by the approximate equation (9). This effect is clearly shown by the curves D and E in Fig. 6.

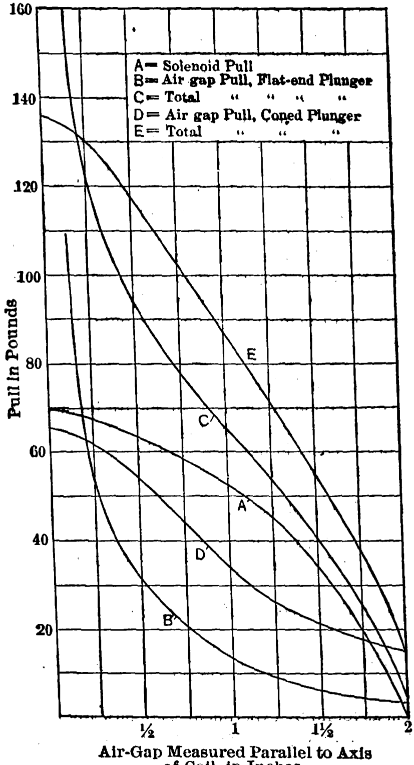

Fig. 6. Pull Curves of D-C. Magnet. —Length of solenoid 3 inches; internal diameter of solenoid 1¾ inches; external diameter 2¾ inches; diameter of plunger 1¼ inches; angle of cone 20°; stop projects 1 inch inside coil; number of turns 300; current 57 amperes.

HORSESHOE-TYPE ELECTROMAGNETS. — Another type of electromagnet which is used quite extensively is the horseshoe-type electromagnet, as shown in Fig. 7. This magnet is not suitable for very long air-gaps, because the leakage increases very rapidly with increasing distance between armature and poles. The total pull on the "armature" K of such a magnet, neglecting the leakage, may be expressed approximately by the relation

$$P = 2.8 \times 10^{-7} A \left(\frac{NI}{2\, l_a + l'} \right)^2 \qquad \text{pounds}, \qquad (10)$$

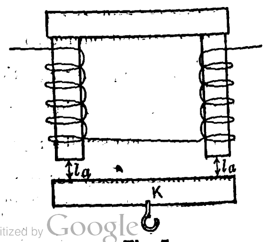

Fig. 7.

where A = cross-section of each pole, in square inches, NI = total ampere-turns,

l_a = length of each air-gap in inches, and l' = length of air-gap equivalent to the reluctance of the iron. This last depends on the permeability and dimensions of the iron part of the circuit; calling l_i the mean length of this iron circuit and μ its permeability, and assuming the mean cross-section of this path to be the same as the cross-section A of each pole, then $l' = l_i/\mu$. A more exact calculation of the pull may be made by calculating, as for a generator field (*see Generators, Direct-current*), the ampere-turns required to establish a given flux density of B lines per square inch in the gap, and then applying equation (3) to determine the pull.

Applications of Horseshoe Type. — This type of electromagnet is frequently used where it is only desired to hold a weight after the armature has come into contact with the poles. A modified form of this magnet whereby the winding is put on the yoke connecting the two poles is used extensively as a no-voltage release on hand starters for direct-current motors (*see Starters, Motor*) and in larger sizes this type of magnet is used for lifting rails, tubes and similar material.

Concentric Lifting Magnets. — A still further modification of this horseshoe magnet has two concentric poles and the winding is arranged concentrically between the two poles. This type of magnet is used as a lifting magnet, either in circular or rectangular shape.

These lifting magnets are especially suitable for lifting pig iron, billets, skull crackers and other magnetic material. The material to be lifted forms in this case the armature of the magnet. The magnetic frame consists of a bell-shaped structure forming the outer pole with a central projection forming the inner pole, the coil being arranged ring-shaped and located concentrically between the inner and outer pole. A circular plate of non-magnetic material mounted between the inner and the outer pole, protects the coil from injury. The voids inside the coil winding are usually filled up with impregnating material, which also serves to make the magnet waterproof.

Magnetic Disc Brakes. — A similar magnet is used for magnetic disc brakes. The magnet is usually mounted on the end plate of the motor and attracts a disc-shaped armature which operates against a spring. When the disc is under the influence of the spring pressure and the magnet deënergized, it presses against a series of stationary and movable discs, the latter being connected with the motor shaft, and causes friction between these parts, which tends to retard and stop the motor. The movement of the armature on these disc brakes is very small, being of the order of ¼ inch.

Magnetic Clutches. — Of similar construction are magnetic clutches. In this case the magnet is mounted on the end of the shaft of the driving machine, whereas the armature, which consists of a circular ring, mounted to a hub by means of a somewhat flexible connection, is connected with the driven member. When the magnet is energized the disc is attracted and takes part in the rotation, thereby driving the second shaft. A pair of collector rings are provided to convey the current from the stationary wires to the rotating magnet. In this case also the movement of the armature is very slight. In order to make the brake release quickly a non-magnetic material is often provided between the magnet and the armature which prevents sticking, due to residual magnetism.

SPEED OF MOVEMENT OF PLUNGER. — In order to obtain quick action, the flux, upon closing the circuit, should reach its full value in as short a time as possible. The flux being a function of the current, the speed depends upon the rapidity with which the current reaches its full value. The time required for the current to reach its full value depends upon the quotient of the inductance L divided by the "effective" resistance R of the circuit. The larger

this ratio $\frac{L}{R}$, which is called the "time constant" of the circuit (*see Transient Electric Phenomena*), the longer the time required for the current to reach its full value. The inductance L is proportional to the square of the number of turns in the solenoid winding and inversely proportional to the total reluctance of the circuit. The effective resistance R depends not only upon the d-c. or ohmic resistance of the winding, but also upon the eddy currents and hysteresis loss set up when the current is changing.

In Fig. 8 is given current-time curve showing the change of the current during the switching-in period of a direct-current magnet. It will be seen that, after the closure of the circuit, the current first rises to a certain value which corresponds to a flux just sufficient to cause a movement of the armature and lift the plunger. As the plunger moves the flux increases, thereby causing a counter electromotive force, which tends to reduce the current. This counter e.m.f. depends upon the speed of the plunger. In the case shown the current drops off continuously until the plunger strikes against the stop, at which moment it has a value of approximately one-third of the value which started the motion of the plunger. After the plunger has come to rest, the current again increases and gradually reaches the value which is dependent upon the terminal voltage and the resistance of the coil.

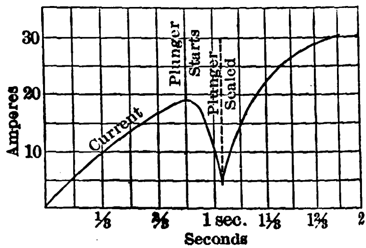

Fig. 8. Current-time Characteristics of D-C. Electromagnet

Methods of Obtaining Quick Action. — To reduce the eddy-current effect, the cross-section of the magnet frame should be as small as consistent with other considerations. Where very quick action is required it is sometimes advisable to slot this frame at right angles to the direction of the eddy currents or laminate it similar to transformers. In such cases it is also advisable to eliminate the brass tube on which the coil is very frequently wound and which acts as a guide for the plunger, or to slot this brass tube parallel to its axis. It is also advisable to slot or laminate the plunger.

Another method of obtaining quick action is to impress at the start a high voltage on the coil and insert resistance into the circuit of the coil as the plunger rises, in order to protect the magnet from overheating. This reduces the ampere-turns at the end of the stroke, which is permissible in most cases, because usually the pull of the magnet increases very rapidly toward the end of the stroke, as is indicated by the formulas given above.

ALTERNATING-CURRENT ELECTROMAGNETS.—Electromagnets for producing a mechanical pull may also be designed to operate on alternating current. The flux in an alternating-current magnet passes through zero twice per cycle. The pull, which varies with the square of the current, therefore becomes zero twice every cycle, and it can be shown that it also varies according to a sine curve when the current is sinusoidal. The average effective pull is one-half of the maximum pull. Whenever the pull is less than the load, there is a tendency for the plunger to move away from the stop, and this causes rattling or humming of the magnet. This humming may be overcome in different ways, one method being to use a "shading coil," described below.

Polyphase Electromagnets. — It can be shown that if three magnets are used and each is supplied with current from one phase of a three-phase source, or if two magnets are used and each is supplied with current from one phase of a two-phase source, then the resultant pull will be constant at any moment, and if the plungers are rigidly connected there will then be no chattering. The most common form of three-phase magnet is shown in Fig. 9. This consists of a core having three poles and a plunger of similar construction. Over each pole there is wound a coil which is supplied from one of the three phases of the circuit. There are various modifications of the polyphase magnet, but their general principle is the same. In calculating the total pull, the pull of each pole is figured separately and the several pulls, which are equal to one another, are combined vectorially, since they differ in time phase (*see Alternating Currents*).

Calculation of Pull of Single-phase Electromagnets, or of One Phase of Polyphase Electromagnets.—The formulas for pull given above for direct-current electromagnets also hold for alternating-current magnets, provided I is taken as the effective value of the current, B as the effective value of the flux density and P as the average or effective value of the pull.

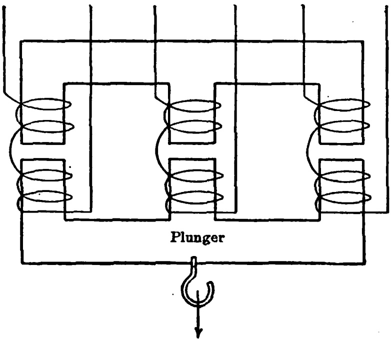

Fig. 9.

In contrast to the d-c. electromagnet, the flux in an a-c. electromagnet for a given impressed e.m.f. is approximately constant irrespective of the length of the air-gap. This is due to the fact that the opposition to the flow of current through the winding is due almost entirely to the back e.m.f., due to the alternation of the flux, and only to a very small extent to the resistance of the winding, the action in this respect being similar to that of a transformer (q.v.) or induction motor (*see Motors*). The back e.m.f. being practically equal to the impressed e.m.f., the flux producing this back e.m.f. is also proportional to the impressed e.m.f., and is therefore practically constant when the impressed e.m.f. is constant.

Since the flux remains practically constant, the current I, as may be seen from equation (4), must vary approximately proportionally to the length of the air-gap l_a; this proportionality holds only approximately, since equation (4) neglects the magnetic leakage and the reluctance of the iron part of the magnetic circuit. The actual variation of the current with the length of the air-gap for a particular a-c. electromagnet is shown in Fig. 10.

Using the same notation as used above for d-c. electromagnets and in addition putting E = effective value of impressed voltage per phase, and f = frequency of impressed voltage in cycles per second, the current taken by each phase of the magnet, neglecting the iron losses, leakage and reluctance of the iron part of the magnetic circuit, will be

$$I = \frac{10^7 E l_a}{2 f N^2 A} \quad \text{amperes.} \tag{11}$$

A more accurate calculation of the current, taking into account the losses and

the magnetic leakage, may be effected by the method used for calculating the current in a transformer (*see Transformers*).

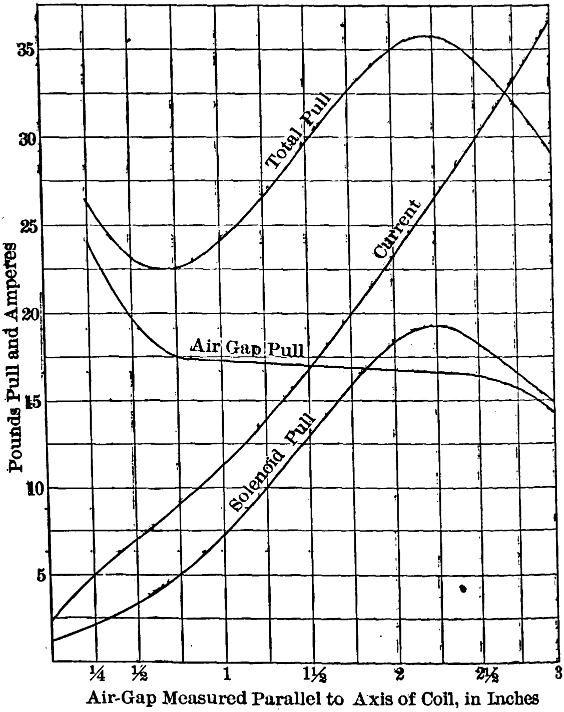

Fig. 10. Pull and Current Curves of A-C. Magnet.—Length of solenoid 5 inches; internal diameter of solenoid 3 inches; external diameter 4½ inches; diameter of plunger 2⅜ inches; stop projects 1½ inches inside of coil; turns 144; voltage 220; frequency 60 cycles per second.

Substitution of the value of the current given by (11) in equation (6) for the total pull on a plunger with a flat end gives the approximate formula

$$P = \frac{10^6 E}{2fN}\left(\frac{kl_a}{l_s} + \frac{72\,E}{fNA}\right) \qquad \text{pounds.} \tag{12}$$

This equation also applies to a coned plunger, when l_a is taken equal to the length of the air-gap perpendicular to the face of the cone.

Fig. 10 shows the pull curve of an alternating-current magnet with flat-end stop and plunger. It will be noted that the current is roughly proportional to the air-gap. The solenoid pull reaches a maximum at an air-gap of about 2¼ inches and then falls again approximately proportional to the air-gap; the air-gap pull is constant over a wide range of the travel. The result is a total pull curve which has a maximum at approximately 2¼ inches and which drops until an air-gap of approximately ¾ inch is reached, and from there on it increases

again, due to the increase of the air-gap pull, the latter being caused by the diminution of the leakage flux as the air-gap decreases.

Limiting Flux Density and Losses in A-C. Electromagnets. — Attention must be paid to the fact that the iron losses, similar to those of the transformer increase with the flux density and therefore the design must be such that the flux density is not too high. The flux density in the iron in the case of a flat-end plunger, from equation (4), which neglects the magnetic leakage and reluctance of the iron part of the magnetic path, is

$$B = \frac{1.6 \times 10^7 E}{fNA} \quad \text{maxwells per sq. in.} \qquad (13)$$

and in the case of a coned plunger, under the same assumptions, from equation (7), is

$$B = \frac{1.6 \times 10^7 E}{fNA \sin \alpha} \quad \text{maxwells per sq. in.} \qquad (14)$$

where α is the cone angle, see Fig. 5.

These relations are approximate only. The magnetizing component of the exciting current, and from it the flux density can be more accurately calculated by the methods employed in the design of transformers or induction motors. See *Transformers* and *Motors, Polyphase Induction.*

The iron and copper losses can also be calculated by similar methods, and from these losses the energy component of the exciting current can be determined. The total current and power factor of the electromagnet can then be deduced.

Shading Coil for Single-phase Electromagnets.—The humming of single-phase magnets may be greatly reduced by introducing a so-called "shading coil" in the pole face. This shading coil is nothing more than a short-circuited secondary winding, consisting of one or more turns, which encloses only part of the total flux passing through the plunger. Due to the leakage reactance of this turn, the current induced in it is out of phase with the inducing flux, so that at the moment when the inducing flux, due to the main winding, is zero, there still remains a flux due to the current in the shading coil, which flux produces a pull. The result is that the combined pull from the main flux and the shading coil flux never becomes zero. Fig. 11 shows the arrangement of the shading coil. This coil is mounted in the plunger or in the plug close to the pole face, in order to reduce the length of the path for the magnetic lines which are interlinked with the shading coil. Naturally the shading coil has no effect with long air-gaps, and it is therefore imperative that a good magnetic contact be obtained when the plunger is in the sealed position to get the greatest possible effect of the shading coil.

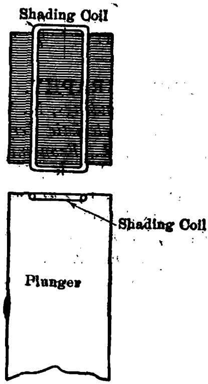

Fig. 11. Shading Coil.

Incidentally the shading coil also increases considerably the maximum pull for a given impressed e.m.f., as the minimum pull is also due to the combined main and local flux. As an example, a plunger magnet without shading coil, which gave a minimum pull of zero and a maximum pull of 28 pounds, had, after the introduction of the shading coil, a minimum pull of 18 pounds and a maximum pull of 143 pounds.

COSTS, WEIGHTS AND DIMENSIONS OF ELECTROMAGNETS. — Due to the great variety in the designs, it is not possible to give unit costs

of electromagnets. The subject of the most economical magnet design has been discussed by Wikander (*Trans. A.I.E.E., 1911, Vol. 30, p. 2019*), but unfortunately the most economical design will usually be found not to be suitable for practical purposes, because it results in a magnet which is too long compared to its diameter, and which usually cannot be incorporated in the machine with which it is to be used. Therefore, magnets as they are found in practical application deviate greatly from the most economical design. Also for the same energy output (usually expressed as inch-pounds or foot-pounds) there is as much as a 1 to 3 variation, depending upon the service conditions as to speed of operation, stroke, etc., which they have to meet. The following table of costs, weights and dimensions of some typical electromagnets is given merely as a rough guide.

Use for which designed	Over-all length, inches	Over-all diameter, inches	Total weight of active iron and copper, pounds	Length of stroke, inches	Pull at beginning of stroke, pounds	Voltage	Watts input at end of stroke	Power factor at end of stroke	Factory cost
1. Relay, D.C.	3¼	2⅛	2.9	⅛	0.15	110–500	9	....	$5.10
2. Relay, A.C.	3¼	2⅛	2.9	⅛	0.10	110–550	15	0.39	6.95
3. Lifting, D.C.	5	3	8	1	8	110–550	50	....	6.40
4. Lifting, D.C.	11	7	80	3	20	110–500	210	....	33.00
5. Lifting, A.C.	5½	4	10	⅞	7	110–550	30	0.30	8.15
6. Lifting, A.C.	14	6¼	90	2½	50	110–550	400	0.31	32.00
7. Brake, D.C.	5¼	8½	72	⅛	160	110–220	50	....	21.00
8. Brake, D.C.	6	15	320	5/32	1260	110–220	210	....	39.00
9. Clutch, D.C.	6½	10	82	⅛	60	110–220	52	....	19.00
10. Clutch, D.C.	7	18	210	⅛	400	110–220	115	....	35.00

ELECTROMETERS. — (*See also Electrodynamometers; Voltmeters: Wattmeters.*) An electrometer is primarily an instrument for measuring potential differences, but under certain conditions may also be used as a wattmeter; in the latter case it is usually called an electrostatic wattmeter. The deflection of the instrument is due to the attraction or repulsion of electrostatic charges. It may be used for either direct- or alternating-current measurements.

There are a great variety of forms of electrometers. On account of the care required in its use, the ordinary quadrant electrometer is seldom employed except for laboratory purposes, but various modifications of the electrometer provided with pointer and scale so as to be direct reading are used commercially for high voltage measurements. Such instruments are known as electrostatic voltmeters; for description see article on *Voltmeters*.

Electrometer versus Galvanometer or Electrodynamometer. — The advantage of the electrometer over the galvanometer or electrodynamometer is that it takes no current when used for constant (d-c.) voltage measurements. Due to its electrostatic capacity, however, it does take a certain amount of charge which should always be allowed for if the capacity of the electrometer is appreciable compared with any other capacity which affects its reading. Also, when used for a-c. measurements, the charging current taken by the electrometer should be allowed for, if this charging current is appreciable. This charging current is usually considerably less than would be taken by an electrodynamometer of the same degree of sensitiveness.

KELVIN QUADRANT ELECTROMETER (Fig. 1). — Two brass quadrants a and a' are connected together and two quadrants b and b' are connected together and these respective pairs are well insulated from one another. The "needle" n (a light aluminum vane) is suspended by a silk, silvered quartz or other fiber and insulated from the quadrants.

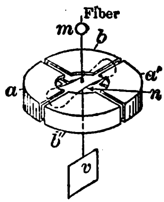

Fig. 1. Quadrant Electrometer

A light aluminum vane v is suspended from the needle by a fine conducting wire and dips into a conducting solution, usually 60 per cent sulphuric acid, which serves as a means of connecting the needle to any external source of p.d. or to the ground. If a conducting suspension is used this may be employed to connect the needle to the external source of potential. The sulphuric acid also keeps the air dry in the case containing the quadrants, and the motion of the vane in the acid damps the vibrations of the needle. The suspension carries a mirror m by means of which the deflection of the needle may be read.

Formulas for Quadrant Electrometer. — In order to obtain a straight line calibration curve the needle must be properly shaped and must be suspended midway (vertically) between the two quadrants and must have a symmetrical zero position with respect to the two quadrants. Under these conditions when the two pairs of quadrants are charged to potentials V_a and V_b and the needle to the potential V_n above any fixed potential, say that of the ground, the angular deflection is

$$D = \frac{1}{K}(V_a - V_b)\left(V_n - \frac{V_a + V_b}{2}\right),$$

where K is a factor, which is practically a constant. The value and constancy of the factor K should be determined by calibration.

There are three ways of using the instrument, as indicated in the diagram;

Fig. 2. E is a known voltage, V the p.d. to be measured, a and b the two pairs of quadrants and n the needle.

Case I. $V = E \pm \sqrt{E^2 - 2KD}$. (*See footnote.*)

Case II. $V = \dfrac{KD}{E}$

Case III. $V = \sqrt{2KD}$.

Cases I and II are applicable to measurements of constant (d-c.) potentials only. Case III may be used for the measurement of either alternating or direct potentials. In the case of alternating potentials V is the *effective* value.

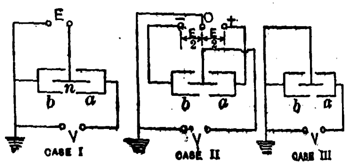

Fig. 2.

Range of Quadrant Electrometers.—The range of a quadrant electrometer when used as in Case I or II depends upon the maximum voltage E which can be impressed between the two pairs of quadrants and between the quadrants and the needle, and also upon the fineness and material of the suspension fiber. Case III is not applicable to the measurement of very low voltages. Electrometers can be purchased suitable for measuring direct voltages as low as about 2 volts, and as high as 50,000 volts, and for alternating voltages as low as about 2 volts and as high as 25,000 volts.

Extension of Range by Use of Auxiliary Condensers (Fig. 3).—By connecting the p.d. to be measured across two condensers in series and measuring the voltage across only one of them, the instrument may be used for the measurement of high voltages of practically any magnitude. The connections are as shown in Fig. 3. If the condensers have no leakage, then

$$V = V_1 \frac{C_1 + C_2 + c}{C_2},$$

where V_1 is the voltage read by the electrometer, C_1 and C_2 the capacities of the two condensers and c the capacity of the condenser formed by the electrom-

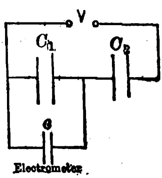

Fig. 3. Electrometer Range Extended by Condenser

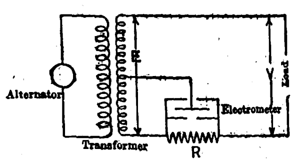

Fig. 4. Electrostatic Wattmeter

eter quadrants and needle. If C_1 and C_2 are large compared with c, then c may be neglected, but the larger C_1 and C_2 the greater will be the charge (and therefore the charging current, in case of an a-c. measurement) taken by the measuring circuit.

Quadrant Electrometer as Electrostatic Wattmeter (Fig. 4).—The quadrant electrometer may be used to measure with a fair degree of precision

* Use the − sign if V is less than E, the + sign if V is greater than E, and call the deflection positive in every case.

very small amounts of power, of the order of 1 watt, when the voltage giving this power is 5000 volts or more. It therefore serves as a very convenient means of measuring the power loss in small samples of insulating materials at high voltages. See paper by E. H. Rayner, *Jour. Inst. Elec. Eng.*, 1912, Vol. 49, p. 3.

The connections used by Rayner are shown in Fig. 4. R is a non-inductive resistance. The needle of the electrometer is connected to the middle point of the high-tension winding of the transformer. *On the assumption that the charging current of the electrometer and the difference in phase between* V *and* E *may be neglected*, the power supplied to the load is

$$P = \frac{2K}{R}D,$$

where K is the instrument constant and D the deflection. The range of the instrument as thus used depends upon the value of R, the higher R the smaller the amount of power which may be read.

However, the higher the value of R the greater the phase difference between E and V if the load current is out of phase with V, and therefore for small power measurements when the load has a low power factor *e.g.*, when it is a condenser, an allowance must be made for this difference in phase angle. Also, when the charging current of the electrometer is comparable in magnitude with the load current a correction must also be applied on this account. These corrections are discussed in detail in Rayner's paper.

COST. — An ordinary Kelvin quadrant electrometer suitable for measuring potentials of from 400 to 1300 volts costs approximately $150.

ELECTRON THEORY. — (*See also Electricity and Magnetism, Principles of; Electrochemistry, Principles of.*) Maxwell's assumption of a displacement current producing magnetic effects similar to those due to an ordinary conduction current is fully justified by the existence of electromagnetic waves (q.v.) whose properties are now well known. In free space these waves travel with the velocity of light; this fact leads to the conception of light waves as being the same as electromagnetic waves, only of shorter wave lengths. However, when this theory is applied to waves in material media, the optical constants as calculated from the theory are found not to agree with the values determined experimentally. The electron theory, namely, the assumption that *in every body, whether charged or uncharged, there exists electricity of both signs distributed not continuously but on discrete particles*, was first introduced* to account for these discrepancies.

Not only does this theory account for these discrepancies in a satisfactory manner, but it also leads to a simple explanation of such phenomena as metallic conduction, the discharge of electricity through gases, the corona effect, etc.

NATURE OF THE ELECTRONS. — The smallest negatively charged particle that it has been found possible to detect is called an electron; the smallest positively charged particle was also originally called an electron, but this name is now usually reserved for the smallest negatively charged particle.

Properties of the (Negative) Electron. — The results of all experiments justify the following assumptions regarding the electron.

1. The charge carried by a single electron is the smallest possible charge which can exist in nature and no charge of electricity can be produced which is not an integral multiple of this charge. The value of the charge carried by a single electron is approximately

$$e = 4.9 \times 10^{-10} \qquad \text{c.g.s. electrostatic units}$$

($= 1.6 \times 10^{-20}$ c.g.s. electromagnetic units). This charge is also equal to that carried by the hydrogen atom in electrolysis. The charge on an electron may be looked upon as the "atom" of electricity. (There is also considerable evidence indicating that the electron *is* electricity pure and simple, having no mass in the ordinary sense; *see below.*)

2. The "effective" mass of an electron may be defined as the force required to give it unit acceleration.† All experiments indicate that the "effective" mass of an electron, as thus defined, is approximately

$$m = 8.9 \times 10^{-28} \qquad \text{grams,}$$

provided the electron is not moving with a velocity greater than one-tenth the velocity of light; for velocities greater than one-tenth that of light the "effective" mass of the electron increases with increase in velocity (*see below*). The mass 8.9×10^{-28} is about one-seventeen hundredth ($1/1700$) that of a hydrogen atom.

Unless otherwise stated, wherever the expression "mass of an electron" is used in this article, it is to be understood that this *effective* mass is meant.

3. An electron having a charge e and moving with velocity v produces the same magnetic field as an elementary length ds of a conduction current of strength i, where $ev = ids$. (*See Electricity and Magnetism, Principles of.*)

4. Every neutral atom of matter contains at least one electron which is held in position by forces analogous to elastic forces, that is, an electron may oscillate

* H. A. Lorentz: Proceedings of the Amsterdam Academy, 1878.

† That is, $f = ma$, where f is the force, a the acceleration, and $m = \frac{f}{a}$ is the "effective" mass.

within the atom, or may be displaced by an impressed electrostatic field. The electrons are always of the same nature irrespective of the substance in which they exist.

5. An electron may be forced from the atom by the influence (mutual repulsion) of a "free" electron moving at a high velocity in its immediate vicinity. This action is usually spoken of as a bombardment, or collision, although it is not necessary to assume that the free electron actually hits the atom.

6. When an electron is expelled from an atom the atom manifests the properties of a positively charged body.

7. In every substance there exists in addition to the electrons within the atoms a certain number of "free" electrons, i.e., electrons which can move freely in the inter-atomic spaces; these free electrons may also pass from one substance to another. Under certain conditions, e.g., in a gas at ordinary pressures, a free electron may attach to itself one or more atoms or molecules.

Properties of the Positive Particle. — Experiment also justifies the following assumptions regarding the positively charged particles:

1. The smallest positive charge that it has been found possible to produce is numerically equal to that of an electron, viz., 4.9×10^{-10} c.g.s. electrostatic units.

2. The smallest possible positive charge is always associated with a particle having a mass of the same order of magnitude as that of an atom, this mass being never less than that of a hydrogen atom.

3. The positively charged particle may be looked upon as an atom from which one or more electrons have been expelled; its mass therefore depends upon the nature of the atom. A "free" positively charged particle may also attach to itself one or more neutral atoms or molecules.

Relation between Electrons and Ions. — The term "ion" is usually reserved to designate any charged body having a mass of the order of magnitude of that of a molecule or atom. In this sense an electron is not an ion, but the positively charged particle is an ion. If, however, the electron becomes attached to an atom or molecule, then this combination forms an ion. In the case of the discharge of electricity through gases at low pressure, the electron, although it is not attached to an atom or molecule, is sometimes called an ion. See also *Electrochemistry, Principles of.*

APPLICATIONS OF THE ELECTRON THEORY. — The hypothesis of electrons, as sketched above, leads to a simple explanation of many of the electrical and optical properties of matter which are otherwise inexplicable. In the following paragraphs will be taken up briefly some of the applications which best illustrate the utility of the electron theory.

Variation of Optical Properties with Wave Length. — The change of refractive index with wave length and the occurrence of selective absorption, emission and reflection can be explained on the assumption that in general there exist in a given molecule several kinds of electrical systems each capable of vibrating with a definite period. The simplest sort of such electrical system is an electron which is subject to forces of restraint varying directly as the displacement of the electron from its position of equilibrium and also to forces of an energy-dissipating character. If, in any one substance, the assumption is made that there exist electrons of as many different periods of vibration as there are wave lengths for which the substance absorbs selectively, it is possible to account for the variation with wave length of the refractive index in a very satisfactory manner and for selective absorption, emission and reflection.

Zeeman Effect. — If a body capable of emitting radiation selectively, for example a sodium flame, is placed in a magnetic field and the light given out is examined by means of a spectroscope, the spectrum lines are found to be

broken up into three or more components if viewed perpendicularly to the lines of magnetic force, and into two or more components if viewed along the lines of force. In the former case, when there are but three component lines, the lines are plane polarized, the plane of polarization of the middle component (which has the same wave length as the original line) being at right angles to the planes of polarization of the other two components; in the latter case, when there are but two component lines, the two components are circularly polarized in opposite directions. These phenomena are known as the Zeeman effect.

If it is assumed that the electrons in the molecules of a substance normally vibrate harmonically, the simple type of Zeeman effect (i.e., a line broken up into only three or two components) can be readily accounted for. Moreover, the observed distance between the component lines when a given spectrum line is split up under the action of a magnetic field is found to agree with the distance as calculated on the assumptions of the electron theory. Or, stated otherwise, quantitative measurements of the Zeeman effect give a means of determining the ratio $\frac{e}{m}$, that is, of the charge carried by an electron to its mass, and the ratio as thus determined is found to agree with the determinations of this ratio by other methods.

By making proper assumptions as to the influence upon any electron of its neighbors it is possible to explain satisfactorily many of the complicated types of Zeeman effect.

Faraday Effect. — When a ray of plane-polarized light is passed through a transparent substance in a magnetic field, the field being parallel to the ray, the plane of polarization is found to be rotated. This phenomenon is known as the Faraday effect. The explanation of this effect in terms of vibrating electrons offers no difficulties. See Campbell's *Modern Electrical Theory*.

Electrical and Thermal Conductivity. — One of the fundamental assumptions of the electron theory is that in conductors there are many electrons which are free to move about among the molecules besides those electrons having fixed positions of equilibrium. It is likely that these electrons are not always the same ones; the molecules are probably continually gaining and losing electrons. It is reasonable to assume that the more free electrons (on the average) in a body the better electrical conductor it is. According to the kinetic theory of matter, the molecules of all substances not at the absolute zero of temperature are in a state of ceaseless agitation; if the assumption is made that the *free* electrons share in the motion of the molecules, then the more free electrons there are in a metal the more rapidly will kinetic energy be communicated from any molecule to neighboring ones, that is, the better conductor of heat the metal will be.

In order to deal quantitatively with the matter some assumption as to numerical values must be made; the one that has been made is that the mean kinetic energy of the electrons is equal to the mean kinetic energy of the molecules. Using the above assumption and also making one as to the relation between the number of electrons per unit volume and the temperature, it has been found possible to explain: 1. Joule's law for the production of heat in a conductor carrying an electric current; 2. the Wiedemann-Franz law, which states that for pure metals the ratio of the thermal to the electrical conductivity is independent of the nature of the metal and is proportional to the absolute temperature; 3. the Peltier and Thomson effects. The theory also throws much light on the nature of the Hall effect.

Electrolysis. — Faraday's laws of electrolysis (*see Electrochemistry, Principles of*) are readily explicable in terms of the electron theory. It is only necessary to assume that each positive univalent ion in the solution is an atom from which

one electron has been expelled, each positive bivalent ion is an atom from which two electrons have been expelled, etc., and that each negative univalent ion is a neutral atom to which one electron has attached itself, each negative bivalent ion is a neutral atom to which two electrons have attached themselves, etc.

Magnetic Properties. — The magnetic properties of bodies may be explained in terms of the electron theory by assuming that the electrons in the molecules of magnetic substances revolve in orbits within the molecule, thus making each molecule produce a magnetic field similar to that produced by a single turn of wire carrying an electric current.

Cathode Rays. — When an electric discharge is passing in a vacuum tube, at a certain value of the pressure of the gas contained in the tube it is noticed that a greenish phosphorescence occurs on the walls of the tube. By placing solid bodies in the tube it is found that the phosphorescence is due to something proceeding in straight lines perpendicularly from the surface of the cathode. The name "cathode rays" has been given to this agent which produces the phosphorescence. These rays are deflected by both electric and magnetic fields and communicate a negative electric charge to an insulated conductor. The assumption that these "rays" consist of a rapidly moving stream of electrons leads to a simple explanation of their properties, both qualitatively and quantitatively. The amount of the deflection of the rays, under the action of magnetic and electrostatic fields, can be calculated on the assumptions of the electron theory, and a comparison of the calculated with the observed deflections shows the two to be in close agreement. Or, stated otherwise, the ratio $\frac{e}{m}$ as calculated from the observed deflections is found to agree with the value of this ratio determined from other data.

Kanalstrahlen. — If the cathode of a tube producing cathode rays is perforated, faint luminous streaks are seen to proceed through these perforations in a direction opposite to that of the cathode rays. The name "kanalstrahlen" has been given to this phenomenon (the German name is very generally retained in English). These rays are also deflected by both electric and magnetic fields but to a lesser extent and in relatively the opposite direction from the deflection of cathode rays, and communicate a *positive* charge to an insulated conductor. In terms of the electron theory these rays are positively charged *ions*. Calculations from actual measurements, making this assumption, show that the charge carried by each of these ions is numerically equal to that of an electron, and that the mass of each ion is never less than the mass of a hydrogen atom, but may be greater, depending upon the nature of the gas and the pressure in the tube. That is, the cathode particle is an electron traveling in one direction and the kanalstrahlen particle is what is left of the atom which has lost an electron, traveling in the opposite direction.

Ionization of a Gas. — Gases at or near atmospheric pressure are normally very good insulators, i.e., have an extremely high insulation resistance. However, a gas may be rendered a fairly good conductor in a number of ways, viz., by passing X-rays through it, letting ultra-violet light fall upon a metal plate immersed in it, subjecting it to the influence of the rays given off by radium, passing it close to a flame or a hot piece of metal or by establishing in it a brush discharge or corona (q.v.). A gas rendered conducting in any of these ways is said to be "ionized."

In terms of the electron theory the conductivity thus given to a gas is attributed to the breaking up of some of the molecules of the gas into positive and negative ions. To account for the observed facts it is necessary to assume that, at pressures of 20 cm. or over, by barometer, the electrons and positive ions thus formed immediately attract molecules to themselves just as an electrified rod

attracts dust particles. Since the force of attraction is independent of the sign of the charge both the positively and negatively charged particles thus produced would act in very much the same manner. In gases at low pressures, however, the electron, or the positive ion, would rarely come within attracting distance of a molecule and even if it did collect molecules about itself a *collision* with a molecule would probably reduce it to its simplest form at once. A collision in gases at high pressure probably has the same effect but the ion very soon reforms owing to the greater number of molecules in its vicinity.

Ionization by Collision—Theory of the Corona.—The electron theory assumes that at least a few free ions (positively charged particles or electrons with one or more molecules attached) exist in every substance. The fewer these free ions, the better the insulating properties of the substance. Under the action of an electric field these ions are given a velocity which depends upon their mass and upon the distance which they can travel before colliding with other molecules or ions. In the case of a gas the "mean free path" is relatively large, being greater the less the density.

The ions present in a gas may therefore acquire, under the action of an electric field, a very considerable velocity. When one of these rapidly moving ions comes very close to a molecule of the gas it exercises a large force of repulsion on the electrons in the molecule and may thereby expel one or more electrons from the atom. The electric field therefore causes a large increase in the number of ions present in the gas and consequently the conductivity of the gas is largely increased.

This is the probable explanation of the formation of the corona (q.v.), granting the existence of a few free ions in the gas to start with. The existence of these ions is rendered extremely probable by the fact that all gases in the natural state have an appreciable conductivity.

Formation of Clouds in Dust-free Ionized Gas.—If a dust-free gas rendered conducting by any of the methods described above is saturated with water vapor and then subjected to an adiabatic expansion, it is found that a cloud of small drops will form and that the drops will be charged. By observing the rate of fall of these drops under the action of gravity alone and also under the action of gravity and a known electric field, the charge on each drop can readily be calculated. (*See J. J. Thomson, Conduction of Electricity through Gases.*) This charge is found to have approximately the value 4.9×10^{-10} electrostatic units or some *exact multiple* of this charge. Small drops carrying electric charges are also very commonly produced in the process of spraying a liquid. The charges carried by such drops have been investigated by numerous observers and have always been found to be exact multiples of the charge 4.9×10^{-10} electrostatic units. These experiments are the justification for assuming that the charge of an electron is 4.9×10^{-10} c.g.s. electrostatic units.

MASS OF THE ELECTRON.—Since to account for the various observed facts noted above it is necessary to assume that a moving electron produces a magnetic field (which assumption is in accord with the experimental fact that a moving charged body of finite dimensions produces a magnetic field), it follows that the total energy of motion of an electron is

$$W = \tfrac{1}{2}\, m_0 v^2 + W_e,$$

where the term $\tfrac{1}{2}\, m_0 v^2$ represents the energy which would be required to give the electron a velocity v *if it had no electric charge whatever*, and W_e is the energy stored in the magnetic field established by the motion of the charge carried by the electron. This expression may also be written

$$\tfrac{1}{2}\,(m_0 + m_e)\, v^2,$$

where $m_e = 2\,W_e/v^2$. The quantity m_0 is the ordinary or mechanical mass of the electron; the quantity m_e is called the "electromagnetic mass" of the electron. The latter, however, is more analogous to the coefficient of self-induction than it is to mechanical mass, since it is part of the expression for the energy of the *magnetic field* established by the moving electron.

The total "effective" mass of the electron is then

$$m = m_0 + m_e.$$

Since it is the total "effective" mass that enters into all calculations of $\frac{e}{m}$ from experimental data, it is impossible by direct experiment to determine m_0 and m_e separately. However, m_e can be calculated in terms of the charge e and the velocity, provided certain assumptions are made regarding the distribution of charge in the electron. Several different formulas have been proposed, based on different assumptions, regarding the distribution of the charge. All these contain a *constant* term independent of the velocity, and *this constant term, within the limits of experimental error, is found to be equal to the total mass m calculated from experimental determinations of the ratio* $\frac{e}{m}$ *and the charge e*, provided the velocity of the electron is less than one-tenth that of light (see next paragraph). Hence the mechanical mass m_0 of the electron is negligible, within the limits of experimental error, compared with the electromagnetic mass m_e.

The above considerations are the basis of the assumption, now generally made by physicists, that the mass of the electron is *entirely* electromagnetic i.e., that the electron is electricity pure and simple. In fact, some physicists go farther and try to explain all mass in terms of electricity. A satisfactory theory of this kind, however, cannot be developed until the properties of the positively charged particle are better understood. See J. J. Thomson, *The Corpuscular Theory of Matter*.

Variation of the Mass of the Electron with Velocity. — When the velocity of the electron approaches that of light both theory and experiment indicate that its electromagnetic mass increases. The formula which best satisfies the experimental facts is that deduced by Lorentz, viz.,

$$m_e = \frac{8.9 \times 10^{-28}}{\sqrt{1 - \left(\frac{v}{V}\right)^2}}$$

where v is the velocity of the electron and V the velocity of light. For $\frac{v}{V}$ less than 0.1 this formula gives a value for m_e constant to within an error of 1 per cent. Since the mechanical mass of the electron (if there is such) is negligible compared with m_e, the above formula also represents, within the limits of experimental error, the variation of the total effective mass with velocity.

ELECTROSTATIC PRECIPITATION OF SUSPENDED PARTICLES. — (*See also Electricity and Magnetism, Principles of.*) Gases containing particles of matter suspended in them, like smoke or smelter fumes, may be purified electrically, the particles being deposited and recovered. The process has been applied with success to a number of installations, by the International Precipitation Co. of San Francisco, operating under the patents of F. G. Cottrell.

Principle. — The essential features of the process are as follows: Two insulated electrodes are placed in a gas containing suspended particles, one electrode being a flat plate of iron or lead and the other a wire covered with a fuzzy semi-conductor such as asbestos. In some plants, the charging electrode is made of wire gauze through which the particle-laden gas is forced to escape. In passing through the gauze the solid particles become electrified and are drawn to the flat electrode. The electrodes are connected to the terminals of a source of direct current, between which is maintained a difference of potential of 20,000 or more volts. The discharge from the fuzzy surface of one electrode electrifies the suspended particles with charges of the same sign. The result is that the particles are repelled from the fuzzy electrode and attracted to the flat plate, on which they are deposited. The source of current is a transformer and a commutator driven by a synchronous motor.

Typical Installations. — This process is in use for the deposition of fumes from smelter plants, powder factories, cement plants, etc. The first commercial installation was at the works of the Du Pont de Nemours Powder Co. at Pinole, Cal., where sulphur trioxide fumes were deposited electrically. One kilowatt at a transformer voltage of 6600 volts was consumed in depositing the fumes from 100 to 200 cubic feet of flue gas per minute. The next installation was at the Selby Smelting and Lead Co. (Vallejo Junct., Cal.), where several tons of lead fumes mixed with arsenic and sulphur trioxide issued daily from the stacks. A stack, which gave forth about 5000 cubic feet of gas per minute, was treated by suspending lead plates 4 inches wide and 5 feet long, four inches apart in several rows, the flue being 4 feet square. Between the plates were suspended lead-covered iron wires covered with a fuzzy coating of mica. These conductors were supported on two sets of insulators. The power consumption was 2 kilowatts. An installation at the Balaklala Smelter Works (Coram, Cal.) was tested with the result that 85 per cent of the solids in the gases were shown to be deposited. At the Coulton Cement Works, Cal., 20 tons of cement dust per day were deposited from flue gas at 450°C.

[W. A. Del Mar.]

ELEMENTS, CHEMICAL. — (*See also Electrochemistry, Principles of; Weights of Materials; Heat and Heat Effects.*) An element is a substance which cannot be further decomposed into simpler substances by any known means of chemical analysis. At the present time about 100 elements (including the radioactive elements) have been discovered. Recent investigations in radioactivity have proved that substances now regarded as stable elements may be undergoing a process of transformation, the rate of which is, however, too slow to be detected by any known means. In the case of other highly radioactive elements the rate of spontaneous transformation is relatively great; thus it has been shown that helium is an element resulting from the disintegration of radium and the unstable elements formed in the process of its breaking up. The "life" of these unstable elements varies from a few minutes to many years.

Atomic Weights. — Elements always combine in definite proportions (or simple multiples of these proportions). It is possible to assign to each element a number such that the relative proportions (by mass) in which two or more elements combine are simple multiples of these numbers. The minimum combining mass or weight of oxygen has been chosen as 16, for certain practical reasons, and in terms of this standard the smallest combining weights of the other elements are determined by experiment. The numbers thus obtained are called "atomic masses" or more commonly "atomic weights." Formerly the atomic weight of hydrogen was taken as unity, in which case the atomic weight of oxygen equalled 15.98. On the atomic theory the atomic weight is proportional to the mass of the atom. The values of the atomic weights of the elements, as revised to 1913 by the International Committee on Atomic Weights, are given in the following table.

The Periodic Law. — The most important relation between the atomic weights was discovered by Mendelejeff and Lothar Meyer and is known as the Periodic Law. This states that "*the properties of the chemical elements are periodic functions of their atomic weights.*" Thus the elements may be arranged according to ascending values of their atomic weights in groups or families in each of which the chemical and physical properties of the elements are related. The existence and properties of several elements have been predicted by the aid of this law before their discovery.

INTERNATIONAL ATOMIC WEIGHTS, 1913.

Element	Symbol	Atomic weight	Element	Symbol	Atomic weight

[H. M. GOODWIN.]

ELEVATORS, ELECTRIC.—(*See also Hoists; Motors, Industrial Applications of.*) Elevators may be divided in two general classes, freight and passenger. The former requires a comparatively slow speed, about 75 feet per minute and, as a rule, only an infrequent starting and stopping. The passenger elevator, on the other hand, requires a speed of from 250 to 500 feet per minute. The lower speed is used for local elevators which may be called upon to stop at every floor. Ability to start and stop the elevator quickly and economically is here of the greatest importance, and the hoisting speed is of minor importance. Express elevators require a much higher speed, but as they generally must operate as locals for a number of the upper floors they are often of the two-speed type.

Power Required. — The horse-power of an elevator motor depends on the load to be raised, the speed of travel and the elevator efficiency, that is, the combined efficiency of the motor, the gear and the drive. It is customary to counterbalance the weight of the cage, and if it is under or overbalanced this amount must be added or deducted from the live load to get the actual load.

$$\text{Horse-power} = \frac{(\text{Unbalanced load in lb.}) \times (\text{Speed of elevator in ft. per min.})}{33{,}000 \times (\text{Efficiency})}$$

An efficiency of 0.50 is generally used in problems of this kind.

As the load is intermittent the motors are generally rated on the basis of 55° C. rise, with full load for one-half hour. The starting torque should be from 2 to 2½ times full-load torque.

Direct-current and Alternating-current Systems are both in general use for elevator service. With the direct-current system the adjustable-speed motor having a small percentage of compound winding is best adapted for obtaining the best control and a smooth acceleration. The series winding is cut out by the controller at normal speed, but is necessary in starting, insuring a smooth quick start, and it is furthermore of great value in the subsequent control of the motor. The best results will be obtained with about 10 to 15 per cent series-field winding.

Very successful service is also obtained with the alternating-current system. Squirrel-cage induction motors should, however, only be selected for slow- and constant-speed freight elevators and where the impairment of the line regulation, caused by the high-starting currents, can be overlooked. For large capacity elevators the squirrel-cage motor is entirely unsuitable, as it cannot be thrown directly on the line without inserting a primary starting resistance. This, however, cuts down the applied voltage and decreases the starting torque. Where squirrel-cage induction motors are used they must be of the high-resistance rotor type so as to provide for a high starting torque.

The polyphase-slip-ring type of induction motor has proven to be very satisfactory for elevator service for speeds up to about 250 or 300 feet per minute. This type of motor has a high starting torque characteristic, and suitable secondary control can readily be provided that will insure a smooth acceleration. For higher speeds two-speed machines are as a rule desirable, which eliminates the alternating-current motor. Dynamic braking (*see Cranes*) is also desirable with high-speed elevators, and in order to accomplish this with alternating-current motors, it would be necessary to provide a small motor-generator set to supply a direct-current excitation to the primary winding of the motor. Therefore, modern high-speed elevators are, as a rule, of the direct-current type.

Elevator Controllers must fulfill the most exacting service requirements. They must insure a smooth acceleration, afford positive speed control under widely varying loads, bring the elevator quickly, but smoothly, to a stop, or

from high to low speeds, regardless of load. Accurate stops at the landings must be made and devices should be provided to protect against slack cable, overtravel, overloads, failure of voltage, etc. Controllers may be of the full-magnet type, the semi-magnet type or the mechanically operated type. High-speed passenger elevators running from about 200 to 600 feet per minute are practically always installed with full-magnet controllers.

Direct-current Control Equipment. — With a direct-current equipment the car is started by moving the car switch or car-controller handle directly to the full on position. This releases the solenoid brake, after which the motor starts with full field strength and with resistance in the armature circuit. After the motor has started, the contactors on the contactor panel automatically cut out the dynamic brake resistance, the armature resistance and the series field, when the motor reaches its normal speed. Current relays limit the current taken during the acceleration to a predetermined value. An overload circuit breaker is provided which opens the circuit, while running, in case an abnormal current would tend to flow. This overload circuit breaker is generally interlocked with the car switch in such a way that should the motor be stopped by the action of the circuit breaker relay, this can be reset from the car by merely moving the control lever to the off position. The control equipment is generally arranged to give two speeds — one, a range of from rest up to the normal speed of the motor, secured by cutting out the armature resistance step by step, and a higher range, up to twice normal speed, secured by inserting resistance in the shunt field of the motor.

In stopping, the controller handle can be brought back to the second point, giving half speed, and then to the first point, which introduces the resistance in series with the armature and shunts the armature with the dynamic brake resistance which is relatively low. In this way it is possible to give a slow landing speed of about 25 per cent of the normal speed and which does not vary very much with the load in the car. Moving the control handle to the off position stops the car. It causes the motor to be disconnected from the circuit at the same time applying the solenoid brake, which is actuated by a spring or weight. The coil of the dynamic brake is connected to the motor armature so that this circuit is kept closed in stopping until the motor comes practically to rest, and the braking effect of the current generated in this local circuit is available to assist the mechanical brake.

Limit switches actuated by the elevator winding drum are provided to stop the elevator at predetermined limits of travel. In addition to these, overtravel switches are also ordinarily provided in the elevator hatchway as an extra precaution. These switches are arranged to open the control circuit on overtravel of the car. The first-named switches are generally connected so that after the car has been automatically stopped at either limit of travel, it is possible for the operator to start the car in the reverse direction only. When the hatchway-limit switches open, it is, however, generally impossible for the operator to reverse the car without first going to the elevator machine, thus insuring attention to the cause which made it necessary for the hatchway-limit switch to operate the car.

An auxiliary switch which will automatically stop the motor in case the cable slackens from any cause, such as the breaking of the cable or the catching of the cage, is also generally provided. It is mounted on one side of the winding drum and operated by a cross arm extending across the drum. Should the cable become slack the movement of the cross arm will serve to trip the switch, opening the control system and stopping the elevator. The slack-cable switch cannot be automatically reset, but after having tripped out must be reset by hand thus also obliging the operator to go to the source of trouble before the elevator can be again operated.

Alternating-current Control Equipment. — As with the direct-current system there are also many types of controllers made for the alternating-current system. The best types are those known as the full-magnet controllers, which are automatic in operation and controlled from a car switch in the same manner as the direct-current type. As stated above, alternating-current motors should preferably not be used for speeds over 250 or 300 r.p.m., because it is not feasible to employ dynamic braking. This means that the car must be slowed down and stopped by the application of the solenoid brake alone, and the speed must therefore be one that will permit of this being done with safety and comfort under all the widely varying conditions met with in elevator service.

A complete alternating-current control equipment generally comprises a contactor panel, a car switch, one or more limit switches, a slack cable switch and a solenoid brake. The solenoid brake is designed to be connected directly to the motor terminals, and when the circuit to the motor is closed the solenoid is energized and the brake retracted. Upon the opening of the main-line circuit, whether this is done intentionally in operating the elevator or is the result of accident, the solenoid is deënergized and the brake is instantly applied. The brake should be designed so as to permit of a gradual rather than an instantaneous braking effect, so as to avoid jarring the car by stopping it too suddenly.

The acceleration is accomplished by a number of alternating-current contactors, these being so connected as to cut a section of resistance out of each of the three phases of the rotor circuit simultaneously, the rate of acceleration being governed automatically by a number of current-limit relays in the rotor circuit.

Energy Consumption. — In all elevators, particularly in those electrically operated, the use of power increases in proportion to the number of starts and stops. This is a natural result of the use of the electric motor, in which the largest part of the energy is required for the process of acceleration, the next largest for electrical and mechanical retardation, and a lesser amount for the actual running speed, with a small proportion devoted to the continuous excitation of the field. It therefore follows that in this form of elevator, which is now so widely used, the main part of the consumption of power is directly related to the number of stops and starts which result from the number of persons carried.. The diversities in results which have been reported from time to time as to the consumption of current by electrical elevators may therefore be attributed to variations in traffic conditions. The results of a series of tests made upon the operation of a one-to-one traction elevator in a ten-story building as reported by R. P. Bolton (*A.S.M.E., 1910*) are given in the table on the following page.

SPECIFICATIONS FOR ELECTRIC ELEVATORS.* — The following memoranda are intended to assist in writing specifications. See also article on *Specifications*.

Performance.—Where elevator is to be situated. Purpose, i.e., whether for passenger or freight service. Characteristics of current supply. Length of run and number of stops. Full running speed and number of feet traveled from rest to full speed. Noiselessness outside of spaces occupied by machinery. Maximum kilowatt-hours per car mile. (This is often supplied by bidder for a given schedule.)

Machinery.—Type of hoisting machinery. Who supplies supports and framing for machines. Details of drum and shaft materials, and minimum diameter. (Drums are usually of grey cast iron and shaft of forged open-hearth steel.) Worm and gear details. The worm shall be of open-hearth steel and the gear of phosphor bronze. Motor details (*see articles on Motors.*) Method of taking up thrust of shaft and drum. Details of brake.

* By W. A. Del Mar.

ENERGY CONSUMED BY AN ELECTRIC ELEVATOR AT VARIOUS LOADS AND STOPS

Machine: One-to-one Electric Traction.
Total Weight of Car: 3956 pounds; Overbalance: 1060 pounds.
Capacity: 2500 pounds at a speed of 500 feet per minute.

Stops at floors No.													
	Up	1 and 9							1, 5 and 9				
	Down	9 and 1							9, 5 and 1				
Distance ..		101 ft. 6 in. one way or per trip = 52 trips per car mile											
Load, lb...		Operator	666	1060	1360	2010	2360	2660	Operator	666	1060	2010	2660
Kw-hr. per car mile..		2.345	2.075	1.945	1.87	2.15	2.495	3.22	3.09	2.855	2.52	2.915	3.85

Stops at floors No.									
	Up	1, 3, 5, 7 and 9				1, 2, 3, 4, 5, 6, 7, 8 and 9			
	Down	9, 7, 5, 3 and 1				9, 8, 7, 6, 5, 4, 3, 2 and 1			
Distance..........		101 ft. 6 in. one way or per trip = 52 trips per car mile.							
Load, lb...........		Operator	666	1060	2010	Operator	666	1060	2010
Kw-hr. per car mile		4.91	4.185	3.975	4.25	7.285	6.75	6.7	7.425

Safety Devices.—(a) Centrifugal governor: When the speed exceeds a stated speed, the car shall be gradually retarded. (b) Machine governor: When speed of car reaches a certain amount, greater than that at which the centrifugal governor acts, and less than that required to throw the safety clutches on the car, the circuit breaker shall open. (c) Limit stops, upper and lower: When the car approaches the limits, the controller circuit shall be automatically opened, and the brake applied. (d) Circuit-breaker details.

Cables.—Description, diameter and minimum number. The number of cables shall be sufficient to prevent any slipping of the cables on the drum when the car is operated under maximum load and contract speed.

Switchboard and Wiring.—Details of switchboard. Details of controller cable, which should be extra flexible and insulated with the best quality rubber.

Shaft Equipment.—Description of shaftway inclosures, with drawings. Elevator pit; general description; whether elevator contractor will find it ready for use and whether any machinery may be installed below the pit. Pent-house; general description; whether elevator contractor will find it ready for use, and whether any machinery may be installed outside or above penthouse

inclosure. Beams for support of sheaves, guides, governors, bumpers, etc. Description and drawings. Whether to be supplied by elevator contractor. Buffers under elevator, description. Counterweights, description; the material is usually grey cast iron. Shaftway fittings, including supports, oil buffers, grating for overhead sheaves, material of sheaves (usually tough grey cast iron), bearing boxes, drip pans, guide rails. The guide rails are usually steel tees of a stated weight per foot. The details of their attachment to the shaft structure should be specified. Doors, details.

Car. — Details of construction, including statement of sides where door or doors are required. Safety clutch, details. Slack-cable device, details. Counterbalance chains shall be attached to bottom of car to compensate for weight of elevator cables.

Cage. — Details of construction, fireproofing, floor details, including finish of floors at edges, folding gate, lighting, emergency door, etc. There shall be no strain on the cage when the safety devices operate. Operating equipment, including controller, emergency switch, lighting switch, safety lever, annunciator in connection with signal system, etc.

Control System. — Control mechanism, description. Number of speeds by controller. Car to stop upon release of lever. Controller shall be out of way of passengers, yet allow operator to keep one hand on the gate while the other is on the switch. Provision shall be made to operate the car from the switchboard when not being operated from within. If the operator reverses while the car is running, the reversal of direction shall be gradual and without shock to passengers. The following operations shall be accomplished by controller: (a) Make and break circuit and reverse motor without destructible arcing at contacts or flashing at brushes. (b) Give easy acceleration of car independently of operator; stopping or starting without shock or jar. (c) Lift brake, cut out starting resistance quietly and operate fields by successive steps in starting. (d) Apply brake and cut in special field resistance in series with armature in stopping in order to attain a retardation of the car prior to the pressure of the brake shoes upon the brake pulley. (e) Other control will be considered.

Signaling and Indicator System. — Details of signaling system. Signals shall indicate correctly the position of the car whatever the motions of the latter. The indicator system shall give the operator in the car a clear signal showing what floor to stop at and whether passengers want to go up or down.

General Matters. — Details of test. Instruction by contractor in use of equipment. During the operation of the cars in the shaft and before its final completion, the contractor shall install on the cars a 6-inch gong, which will ring automatically at each floor up and down the shaft as a warning signal. Lubrication details. Painting details. Tools to be supplied.

ENDOSMOSE OR ELECTRIC OSMOSIS. — (*See also Electrochemistry, Principles of.*) An electric current flowing through a porous partition, or capillary opening, filled with conducting liquid causes a flow of the liquid through the partition or opening. This phenomenon is known as endosmose or electric osmosis (*see Electrochemistry, Principles of*).

The quantity of a given liquid which is carried through a given porous diaphragm in a definite time varies directly with the current strength and is independent of the area and thickness of the diaphragm. The quantity varies with the nature of the solution, being greater with liquids of high specific resistance. The direction of flow is from positive to negative electrode.

Applications of Endosmose. — Endosmose may be utilized to remove water from wet substances. Thus if a wooden box be equipped with perforated metallic plates at opposite ends and be filled with wet turf and current circulated through the turf from one end to the other, water will ooze out of the perforations of the cathode plate. Endosmose is utilized in tanning processes to accelerate the passage of tanning fluids through the hides, and efforts are being made to utilize it for drying peat, extracting sap and similar purposes.

Endosmose of Negative Feeders. — If electric conductors covered with a saturated braid or a number of such braids be made the cathode of a water bath and say 110 volts applied between anode and cathode, the braid will blister in a few minutes and the blisters will finally burst, grounding the conductor to the water. The same action goes on at lower voltages at a proportionately lower rate, but with equal certainty. Consequently weatherproof conductors otherwise uninsulated are useless for negative feeders on railway circuits. No action is observable if the wire be made the anode instead of the cathode. The same phenomenon is said to be observable with rubber insulation, but the writer has tried several samples of high-grade American compounds made with 30 per cent of Para rubber and obtained no signs of endosmose after subjecting them for a week to a pressure of 110 volts. C. H. Wordingham (*Elect. Engineer, London, Vol. 26, 1900, p. 93*) found, however, that certain makes of rubber are porous and water may enter and eventually destroy the whole of the rubber on the negative conductors. For this reason insulation of low specific resistance should never be used on negative feeders. For the same reason it is not practical to maintain a negative contact rail on electric railways, below earth potential, as the insulators soon become saturated with moisture and thereby become conductors. Thus S. B. Fortenbaugh, relating the experience of the Tube Railways in London, says:

1. That the difference of potential between the positive conductor and earth is always normally considerably greater than the potential existing between the negative conductor and earth.

2. That a reversal of polarity is always instantly accompanied by a considerable increase in the normal leakage current between the positive and negative conductor.

3. The insulation of the negative conductor to earth cannot be indefinitely maintained.

Effect of Endosmose on Insulation Measurements. — When testing wires having insulation of low specific resistance, endosmose may further lower the resistance if the wire is negative to the water bath.

[W. A. Del Mar.]

EQUATIONS. — (*See also Complex Numbers; Errors of Observation; Logarithms; Vectors.*) The subjects treated in this article are

QUADRATIC EQUATION. — The solution of

$$ax^2 + bx + c = 0$$

is

$$x = \frac{-b \pm \sqrt{b^2 - 4ac}}{2a}$$

CUBIC EQUATION. — The solution of the general cubic equation of the form

$$ax^3 + 3bx^2 + 3cx + d = 0 \qquad (1)$$

is obtained as follows: Put

$$y = ax + b$$

$$H = b^2 - ac$$

$$G = a^2d - 3abc + 2b^3$$

then (1) becomes

$$y^3 - 3Hy + G = O. \qquad (2)$$

The nature of the roots of this equation depends upon the algebraic sign of H and the relative numerical magnitudes of G and H.

Case I. H positive and G numerically less than $2H\sqrt{H}$. (G may be either positive or negative.) Put

$$\phi = \frac{1}{3}\sin^{-1}\left[\frac{G}{2H\sqrt{H}}\right]$$

then the three roots of (2) are

$$\begin{aligned} y_1 &= 2\sqrt{H}\sin\phi \\ y_2 &= 2\sqrt{H}\sin(\phi + 120) \\ y_3 &= 2\sqrt{H}\sin(\phi - 120) \end{aligned} \qquad (3)$$

and all three roots are real.

Case II. H positive and G numerically greater than $2H\sqrt{H}$. Put

$$u = \frac{1}{3}\cosh^{-1}\left[\frac{\pm G}{2H\sqrt{H}}\right]$$

the plus sign to be used when G is positive, the negative sign when G is negative thus making $\cosh 3u$ positive in either case.

Then the three roots of (2) are

$$\begin{aligned} y_1 &= \mp 2\sqrt{H}\cosh u \\ y_2 &= \pm\sqrt{H}\cosh u + \sqrt{-3H}\sinh u \\ y_3 &= \pm\sqrt{H}\cosh u - \sqrt{-3H}\sinh u \end{aligned} \qquad (4)$$

the upper signs to be used when G is positive, the lower when G is negative. The first root in this case is real, the other two being complex quantities. See articles on *Complex Quantities* and *Hyperbolic Functions.*

Case III. H negative and G any value. Put

$$u = \frac{1}{3} \sinh^{-1} \left[\frac{\mp G}{2 H \sqrt{-H}} \right]$$

the negative sign to be used when G is positive, the positive sign when G is negative, thus making $\sinh 3u$ positive in either case. Then the three roots of (2) are:

$$\begin{aligned} y_1 &= \mp 2 \sqrt{-H} \sinh u \\ y_2 &= \pm \sqrt{-H} \sinh u + \sqrt{3H} \cosh u \\ y_3 &= \pm \sqrt{-H} \sinh u - \sqrt{3H} \cosh u \end{aligned} \tag{5}$$

the upper sign to be used when G is positive, the lower sign when G is negative. The first root in this case is real, the other two complex quantities.

Note that in each case the sum of the three roots is zero. Also, in the special case when $G = 2H\sqrt{H}$, the angle ϕ is 30°, and therefore from (3) the three roots are $\sqrt{H}$, $\sqrt{H}$ and $-2\sqrt{H}$; this also follows from (4).

Examples. — *Case I.*

$$y^3 - 6y + 2 = 0.$$

$H = 2$ and is positive and $G = 2$ and is less than $2H\sqrt{H}$.

$$\phi = \frac{1}{3} \sin^{-1} \left[\frac{2}{4\sqrt{2}} \right] = 6.90°$$

whence $y_1 = +0.3399$; $y_2 = 2.2618$; $y_3 = -2.6018$.

Case II.

$$y^3 - 3y + 4 = 0.$$

$H = 1$ and is positive and $G = 4$ and is greater than $2H\sqrt{H}$.

$$u = \frac{1}{3} \cosh^{-1} 2 = 0.439$$

whence $y_1 = -2.196$; $y_2 = 1.098 + 0.785\sqrt{-1}$; $y_3 = 1.098 - 0.785\sqrt{-1}$.

Case III.

$$y^3 + 6y + 2 = 0.$$

In this case, $H = -2$ and $G = 2$

$$u = \frac{1}{3} \sinh^{-1} \frac{-2}{-4\sqrt{2}} = 0.1155$$

$$\begin{aligned} y_1 &= -0.3275 \\ y_2 &= 0.1638 + 2.467\sqrt{-1} \\ y_3 &= 0.1638 - 2.467\sqrt{-1} \end{aligned}$$

SIMULTANEOUS EQUATIONS. — Given n independent equations in n unknowns, these n equations fix the values of each of the n unknowns. To solve such a set of simultaneous equations in x, y and z, say, solve each of

the three equations for x in terms of y and z. Equating these three values for x gives two equations in y and z. Solving each of these two equations for y in terms of z and equating these two values of y gives a single equation in z. The solution of this last equation then gives the value of z. Then substitute this value of z in either of the equations in y and z, and solve for y. Then substitute these values of y and z in any one of the original equations and solve for x.

Determinants. — In the case of linear simultaneous equations (i.e., when x, y and z occur only to the first power), the equations may be solved by determinants. This method is a considerable time saver when the number of unknowns is greater than three, but when the number of unknowns is three or less the straight substitution method is preferable.

The determinant of a set of simultaneous equations is formed by writing the equations one below the other with the same unknown in the same relative position in each. The block of numbers forming the coefficients of the unknowns is called the determinant. For example, the determinant of the equations

$$\begin{aligned} w + x + y + z &= 6 \\ w + y + 3z &= 4 \\ w + 2x + 3y &= 1 \\ w + 3x + z &= 3 \end{aligned}$$

is

$$D = \begin{vmatrix} 1 & 1 & 1 & 1 \\ 1 & 0 & 1 & 3 \\ 1 & 2 & 3 & 0 \\ 1 & 3 & 0 & 1 \end{vmatrix}$$

The values of any one of the unknowns, say y, is found by writing a second determinant, D_y, exactly like the determinant D, except that the constants forming the right-hand members of these equations are substituted for the coefficients of y in the determinant, that is

$$D_y = \begin{vmatrix} 1 & 1 & 6 & 1 \\ 1 & 0 & 4 & 3 \\ 1 & 2 & 1 & 0 \\ 1 & 3 & 3 & 1 \end{vmatrix}$$

Then
$$y = \frac{D_y}{D}$$

and similarly for the other unknowns.

The value of any determinant is found by making use of the following rules:

(1) If a determinant has two equal rows or columns, it is equal to zero.

(2) To any row or column one may add or subtract any number of times any other row or column without altering the value of the determinant.

(3) To multiply any row or column by a number is the same as multiplying the determinant by that number.

(4) If all the terms in a row or column except one are zero, the determinant reduces to one of a lower order which may be obtained by striking out the row and column which intersect at the term in question, and multiplying the whole by that term, changing the sign of this term, however, if it is removed by an odd number of terms from the principal diagonal. The principal diagonal is

the line of terms beginning at the upper left-hand corner and ending at the lower right-hand corner. Thus,

$$\begin{vmatrix} 1 & 2 & 8 & 5 \\ 3 & 4 & 6 & 9 \\ 0 & 3 & 0 & 0 \\ 6 & 7 & 4 & 3 \end{vmatrix} = -3 \begin{vmatrix} 1 & 8 & 5 \\ 3 & 6 & 9 \\ 6 & 4 & 3 \end{vmatrix}$$

the principal diagonal being that with the figures 1, 4, 0 and 3. It is immaterial whether the distance from the diagonal is counted along a row or a column.

(5) The value of a determinant of the second order is

$$\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} = a_1 b_2 - a_2 b_1$$

The reduction of determinants is effected by altering the terms according to the above rules until a row or column is obtained in which all terms but one are zero. This enables a reduction of order to be effected in accordance with rule 4. Reductions are continued until one of the second order is obtained.

Example. — By rule (2), the determinant D given above may be written as follows, the top row being subtracted from each of the others.

$$D = \begin{vmatrix} 1 & 1 & 1 & 1 \\ 0 & -1 & 0 & 2 \\ 0 & 1 & 2 & -1 \\ 0 & 2 & -1 & 0 \end{vmatrix}$$

By rule (4) this reduces to

$$D = \begin{vmatrix} -1 & 0 & 2 \\ 1 & 2 & -1 \\ 2 & -1 & 0 \end{vmatrix}$$

By rule (3) this may be written

$$D = \frac{1}{2 \times 2} \begin{vmatrix} -2 & 0 & 4 \\ 2 & 4 & -2 \\ 2 & -1 & 0 \end{vmatrix}$$

By rule (2), adding the top row to each of the others, this reduces to

$$D = \frac{1}{2 \times 2} \begin{vmatrix} -2 & 0 & 4 \\ 0 & 4 & 2 \\ 0 & -1 & 4 \end{vmatrix}$$

which by rule (4) reduces to

$$D = \frac{-2}{2 \times 2} \begin{vmatrix} 4 & 2 \\ -1 & 4 \end{vmatrix}$$

whence by rule (5) $\qquad D = -\frac{1}{2}(4 \times 4 + 1 \times 2) = -9.$

Similarly, $\qquad D_y = 21.$

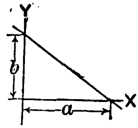
and therefore $\qquad y = -\frac{21}{9} = -2.333.$

Similarly, $\qquad w = 13.33, \quad x = -2.667, \quad z = +2.333.$

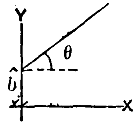
EQUATIONS OF COMMON CURVES.

Straight Line. —

$$\frac{x}{a} + \frac{y}{b} = 1$$

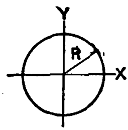


or $\quad y = x \tan\theta + b.$



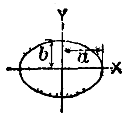
Circle. —

$$x^2 + y^2 = R^2.$$



Ellipse. —

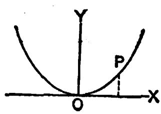
$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1.$$



Parabola (Vertical). —

$$y = kx^2$$

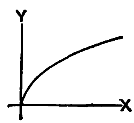
where k is a constant.



Parabola (Horizontal). —

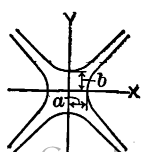
$$y = k\sqrt{x}$$

where k is a constant.



Hyperbola. —

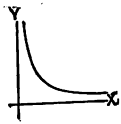
$$\frac{x^2}{a^2} - \frac{y^2}{b^2} = 1.$$



Rectangular or Equilateral Hyperbola.—

$$y = \frac{k}{x}$$

where k is a constant.

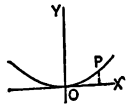


Catenary.—

$$y = \frac{1}{k}\left[\cosh kx - 1\right]$$

where k is a constant. The length of arc from O to P is

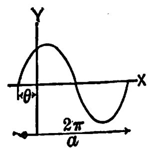
$$\lambda = \frac{1}{k}\sinh (kx).$$



See tables in article on *Hyperbolic Functions*.

Sinusoid.—

$$y = A \sin (ax + \theta).$$



DIFFERENTIAL EQUATIONS.—Differential equations of the following forms are met with in the theory of alternating and transient currents.

The following notation is used: $\epsilon = 2.7183 \ldots$ = base of natural system of logarithms; x, y, u, w are variables. A, ϕ, γ, and θ are integration constants. Other letters represent known constants.

$$\frac{dy}{dx} = ay. \qquad (1)$$

Solution: $$y = A\epsilon^{ax}.$$

$$\frac{dy}{dx} + ay = 0. \qquad (2)$$

Solution: $$y = A\epsilon^{-ax}.$$

$$\frac{dy}{dx} + ay = b. \qquad (3)$$

Solution: $$y = \frac{b}{a}[1 - A\epsilon^{-ax}].$$

$$\frac{d^2y}{dx^2} = -a^2y. \qquad (4)$$

Solution: $$y = \sin (ax + \phi).$$

$$\frac{d^2y}{dx^2} = a^2y. \qquad (5)$$

Solution: $$y = A \sinh (ax + \phi).$$

$$\frac{d^2y}{dx^2} + 2u\frac{dy}{dx} + (u^2 + a^2)\,y = 0. \tag{6}$$

Solution:

Case I. a^2 positive: — $y = A\epsilon^{-ux}\sin(ax + \phi)$.
Case II. a^2 negative: — $y = A\epsilon^{-ux}\sinh(ax + \phi)$.
Case III. $a^2 = 0$: — $y = A\,(x + \phi)\,\epsilon^{-ux}$.

$$\frac{d^2y}{dx^2} + 2a\frac{dy}{dx} + (u^2 + a^2)\,y = B\sin(\omega x + \theta). \tag{7}$$

The complete solution of this equation consists of the solution of No. 6 plus the term

$$\left(\frac{B\sin\delta}{2\,uw}\right)\sin(\omega x + \theta - \delta), \tag{a}$$

where

$$\delta = \tan^{-1}\frac{2\,u\omega}{a^2 + u^2 - \omega^2}.$$

For each additional sine term added to the right-hand member of the equation, there will be a corresponding term of the same form as (*a*) in the solution.

$$\frac{d^ny}{dx^n} + a_{n-1}\frac{d^{n-1}y}{dx^{n-1}} + \ldots a_1\frac{dy}{dx} + a_0y = B\sin(\omega x + \theta). \tag{8}$$

Solution:

$$y = A_1\epsilon^{m_1x} + A_2\epsilon^{m_2x} + \ldots A_n\epsilon^{m_nx} + KB\sin(\omega x + \theta + \delta),$$

where m_1, m_2, etc., are the n roots of the equation

$$m^n + a_{n-1}m^{n-1} + \ldots a_1m + a_0 = 0,$$

and k and δ are found by substituting the $KB\sin(\omega x + \theta + \delta)$ by itself in the given differential equation and equating the coefficients of $\sin(\omega x + \theta)$ and $\cos(\omega x + \theta)$ respectively on the two sides of the resulting equation. When the second member of the differential equation is a constant, B, the sine term in the solution becomes simply $\frac{B}{a_0}$.

Note that all of the preceding equations are merely special cases of the general equation (8).

$$\frac{d^2y}{dx^2} + 2u\frac{dy}{dx} + (u^2 - q^2)\,y = \frac{1}{c^2}\frac{d^2y}{dz^2}. \tag{9}$$

The complete solution of this equation contains an infinite number of terms of the form

$$y = \epsilon^{-(u-s)x}\left[A_1\epsilon^{mz}\sin(\omega x + nz + \phi_1) + A_2\epsilon^{-mz}\sin(\omega x - nz + \phi_2)\right], \tag{a}$$

where A_1, ϕ_1, A_2, ϕ_2 and two of the four constants ω, s, m and n are integration constants (fixed by the terminal conditions). The values of m and n in terms of ω and s are

$$m = c\sqrt{ab}\cos\frac{\eta + \epsilon}{2},$$

$$n = c\sqrt{ab}\sin\frac{\eta + \epsilon}{2},$$

where

$$a = \sqrt{(s+q)^2 + \omega^2}, \qquad \epsilon = \tan^{-1}\left(\frac{\omega}{s+q}\right),$$

$$b = \sqrt{(s-q)^2 + \omega^2}, \qquad \eta = \tan^{-1}\left(\frac{\omega}{s-q}\right).$$

The values of ω and s in terms of m and n are

$$\omega = \frac{\sqrt{FG}}{c} \cdot \cos\frac{\alpha+\beta}{2},$$

$$s = \frac{\sqrt{FG}}{c} \sin\frac{\alpha+\beta}{2},$$

where

$$F = \sqrt{(n+cq)^2 + m^2}, \qquad \alpha = \tan^{-1}\left(\frac{m}{n+cq}\right),$$

$$G = \sqrt{(n-cq)^2 + m^2}, \qquad \beta = \tan^{-1}\left(\frac{m}{n-cq}\right).$$

The solution of equation (9) may also be written as a series of terms of the form

$$y = M\epsilon^{-(u-s)x} \sin(\omega x + \phi + \mu), \tag{b}$$

where

$$M = \frac{A}{\sqrt{2}} \sqrt{\cosh 2(mz+\gamma) + \cos 2(nz+\theta)},$$

$$\tan \mu = \tanh(mz+\gamma) \tan(nz+\theta),$$

where A, ϕ, γ and θ are integration constants, and the relations between the other constants ω, s, m and n are the same as above.

In the special case when $q = 0$, the solution of equation (9) is

$$y = \epsilon^{-ux}[f_1(\omega x + nz) + f_2(\omega x - nz)], \tag{c}$$

where f_1 and f_2 are any two arbitrary functions and w and n are connected by the relation

$$\frac{\omega}{n} = \frac{1}{c}.$$

$$\frac{d^2y}{dx^2} + \frac{1}{x}\frac{dy}{dx} = 4\,a^2y. \tag{10}$$

Solution is an infinite series:

$$y = A\left[1 + (ax)^2 + \frac{(ax)^4}{2^2} + \frac{(ax)^6}{(3!)^2} + \frac{(ax)^8}{(4!)^2} + \ldots\right]. \tag{a}$$

This series is absolutely convergent for all values of x, but for $ax > 1$ the following approximate series is more convenient and sufficiently accurate.

$$y = \frac{B\epsilon^{2ax}}{\sqrt{2\,ax}}\left[1 + \frac{1}{16\,ax} + \frac{3^2}{2\,(16\,ax)^2} + \frac{3^2.5^2}{3!\,(16\,ax)^3} + \frac{3^2.5^2.7^2}{4!\,(16\,ax)^4}\right]. \tag{b}$$

[W. A. Del Mar.]

ERRORS OF OBSERVATION. — When a quantity is measured with all possible accuracy many times in succession, the numbers expressing the results are found to differ by amounts, which, although generally small, are occasionally considerable in comparison with the quantity measured. Though these differences may be decreased by improved methods, better instruments or greater skill, they can never be entirely removed. They are known as the errors of observation. The following formulas, which are derived from the Theory of Least Squares, apply to such errors and not to errors which can be eliminated by correcting mistakes of the observer or defects of instruments or methods of observation. *That is, they apply only to errors which may be either positive or negative, the chance of a positive error occurring being exactly the same as the chance of a negative error occurring.*

Weighted Observations. — Sometimes in spite of the care with which observations are taken, there are reasons for believing that some observations are better than others. In this case the observations are given different "weights" or numbers expressing their relative practical worth. A weighted observation is an observation multiplied by its weight.

PROBABLE VALUE OF SEVERAL OBSERVATIONS. — The most probable value of a quantity which is observed directly several times with equal care is the arithmetical mean of the measurements.

Example. — The length of a room (in feet) is measured ten times with the following results:

20.05	20.06	19.98	19.99	20.00
20.07	20.01	20.05	19.95	19.98

The arithmetical mean of these lengths is 20.01 feet, which is accordingly the probable length of the room.

The most probable value of a quantity which is observed directly several times, but where the observations have different weights, is equal to the sum of the weighted observations divided by the sum of the weights.

Example. — In the above example if the fourth and fifth observations are twice as reliable as the others, and the seventh three times as reliable, the most probable value would be the sum of 20.05, 20.06, 19.98, (19.99 × 2), (20.00 × 2), 20.07, (20.01 × 3), 20.05, 19.95 and 19.98, divided by 14, which is equal to 20.01, which happens in this instance to agree with the unweighted average.

PROBABLE ERROR OF ANY ONE OF SEVERAL OBSERVATIONS. — The probable error of a number of direct observations made with equal care is found by the following formula:

$$r = 0.6745 \sqrt{\frac{\Sigma v^2}{n-1}},$$

where

n = number of observations,
r = probable error of a single observation,
v = residuals found by subtracting each measurement from the arithmetical mean.

Example. — In the example cited above, $n = 10$. The values of v in the order of the observations given above are as follows:

+0.04	+0.05	−0.03	−0.02	−0.01
+0.06	0	+0.04	−0.06	−0.03

The sum of the squares of these quantities is 0.0152. The probable error in any one of the ten observations is

$$r = 0.6745 \sqrt{\frac{0.0152}{9}} = 0.0277.$$

The probable error of each of a number of direct observations, where the observations have different weight, is found by the following formula, in which p represents the weight of an observation.

$$r_1 = 0.6745 \sqrt{\frac{\Sigma pv^2}{n-1}}.$$

Example. — In the example cited above for weighted observations, the values of v are the same as the values of v in the preceding example.

The values of pv^2 are as follows:

0.0016	0.0025	0.0009	0.0008	0.0002
0.0036	.0	0.0016	0.0036	0.0009

and their sum is 0.0157.

Hence the probable error of a single observation

$$r_1 = 0.6745 \sqrt{\frac{0.0157}{9}} = 0.0282.$$

PROBABLE ERROR OF THE ARITHMETICAL MEAN. — If

r = probable error of a single observation,
n = number of observations,
r_0 = probable error of the arithmetical mean,

$r_0 = \dfrac{r}{\sqrt{n}}$ for observations of equal weight, or

$r_0 = \dfrac{r_1}{\sqrt{\Sigma p}}$ for unequal weight.

Example. — In the example cited above for observations of equal weight, $r = 0.0277$ and $n = 10$, and $r_0 = 0.0277/\sqrt{10} = 0.0088$.

In the example cited above for observations of unequal weight, $r_1 = 0.0282$ and $\Sigma p = 14$, and $r_0 = 0.0282/\sqrt{14} = 0.0075$.

It should be noted that the probable error of the mean decreases inversely as the square root of the number of observations.

Example. — The probable error in making a single reading of a watt-hour meter on an electric locomotive is 5 per cent, after all constant sources of error have been eliminated. If 25 locomotives are used, what will be the probable error in the total energy consumption obtained, by adding the watt-hour meter readings? Answer, one per cent.

$$r_0 = \frac{5}{\sqrt{25}} = 1.$$

PROBABLE ERROR IN A RESULT CALCULATED FROM THE MEANS OF SEVERAL OBSERVED QUANTITIES. — Let Z = a sum or difference of several independent quantities.

Let r_1, r_2, r_3, etc., be the probable errors in these quantities. Then the probable error of Z is equal to

$$\sqrt{r_1^2 + r_2^2 + r_3^2 + \text{etc.}}$$

Let $Z = Az$, where z is an observed quantity, and A, a known number. Let be the probable error in z. Then the probable error in Z is Ar.

Let Z be the product of two independently observed quantities z_1 and z_2 whose probable errors are r_1 and r_2 respectively. Then the error in Z is equal to

$$\sqrt{z_1^2 r_2^2 + z_2^2 r_1^2}.$$

Let Z be any function of the independently observed quantities z_1, z_2, z_3, etc., whose probable errors are r_1, r_2, r_3, etc. Then the probable error in Z is equal to

$$\sqrt{\left(\frac{dZ}{dz_1}\right)^2 r_1^2 + \left(\frac{dZ}{dz_2}\right)^2 r_2^2 + \left(\frac{dZ}{dz_3}\right)^2 r_3^2 + \text{etc.}}$$

METHOD OF LEAST SQUARES. — A set of simultaneous equations containing more equations than unknowns cannot have any exact solution unless the superfluous equations are deducible from the others. They may, however, have a most probable solution which is such that the sum of the errors remaining after corrections for the deduced values of the unknowns shall be a minimum. This result is obtained as shown in the following example:

$$\begin{aligned} s - t + 2u &= 3, \\ 3s + 2t - 5u &= 5, \\ 4s + t + 4u &= 21, \\ -s + 3t + 3u &= 14. \end{aligned}$$

The coefficients of s are 1, 3, 4 and -1. Multiplying by these coefficients:

$$\begin{aligned} s - t + 2u &= 3, \\ 9s + 6t - 15u &= 15, \\ 16s + 4t + 16u &= 84, \\ s - 3t - 3u &= -14. \end{aligned}$$

Add these equations and obtain $27s + 6t = 88$.

The coefficients of t are -1, 2, 1 and 3. Multiply the original equations by these coefficients.

$$\begin{aligned} -s + t - 2u &= -3, \\ 6s + 4t - 10u &= 10, \\ 4s + t + 4u &= 21, \\ -3s + 9t + 9u &= 42. \end{aligned}$$

Add these equations and obtain $6s + 15t + u = 70$.

The coefficients of u are 2, -5, 4 and 3. Multiply the original equations by these coefficients.

$$\begin{aligned} 2s - 2t + 4u &= 6, \\ -15s - 10t + 25u &= -25, \\ 16s + 4t + 16u &= 84, \\ -3s + 9t + 9u &= 42. \end{aligned}$$

Add these equations and obtain $t + 54u = 107$.

The equations

$$\begin{aligned} 27s + 6t \quad\quad &= 88, \\ 6s + 15t + u &= 70, \\ t + 54u &= 107, \end{aligned}$$

are then solved in the ordinary way, the solution being

$$s = 2.47, \quad t = 3.56, \quad \text{and} \quad u = 1.92.$$

BIBLIOGRAPHY. — The subject of error of observation is very fully treated in *A Text Book on the Method of Least Squares*, by Mansfield Merriman.

[W. A. DEL MAR.]

EXPLOSIVES. — Explosives may be divided into two classes: progressive and detonating explosives. A progressive explosive is one which burns quickly but not instantaneously. The inner parts of progressive explosives do not burn until the outer parts are consumed so that the combustion takes place gradually. The common progressive explosives are the charcoal and nitrocellulose powders. In detonating explosives the explosive reaction takes place almost simultaneously throughout the substance. The explosive substance is then converted instantaneously into a gas of great volume. The common detonating explosives are guncotton, nitroglycerine, dynamite, explosive gelatin, picric acid derivatives and fulminate of mercury.

Black Powder consists of 75 parts potassium nitrate, 15 parts charcoal and 10 parts sulphur by weight. After being ground to a powder, water is added and the mixture is pressed into cakes and dried. The cakes are then broken into grains and sifted through screens. Prismatic perforated powder is made by pressing the granulated powder in moulds, the mixture being moistened in the process.

Brown Powder consists of 80 parts potassium nitrate, 16 parts charcoal, 3 parts sulphur and 1 part water by weight. In black powder the charcoal is made from wood, while in the brown powder the charcoal is made from rye-straw, the resultant powder being slower burning than black powder. The process of manufacture is the same as with black powder.

Smokeless Powders. — These are commonly made of nitrocellulose powders, which differ from the black or brown charcoal powders in that the mixture is a chemical instead of a mechanical one. Nitrocellulose is obtained by treating cellulose, usually cotton waste, with nitric acid. The nitrocellulose is mixed with ether, being thus converted into a "colloid," and assumes a form devoid of cellular structure. This colloided nitrocellulose, when pressed into perforated prismatic grains, forms smokeless powder. The English smokeless powder, Cordite, is composed of 37 parts colloided nitrocellulose, 58 parts nitroglycerine and 5 parts vaselin.

Guncotton is an uncolloided nitrocellulose containing about 12.9 per cent of nitrogen. It retains the complete cotton structure and can only be distinguished from cotton by its rough feeling. It is compressed into cakes and when stored it is kept wet, as it is then non-explosive except with a powerful detonator.

Nitroglycerine is a nitrate of glycerine and is made by treating pure glycerine with nitric acid. Commercial nitroglycerine is a yellowish oily liquid without odor. It has a sweet taste and burns the tongue. It is poisonous when absorbed through the mouth, nostrils or skin. It is exploded by shock, heating or friction. Nitroglycerine is seldom used in the pure state because of the danger in handling it.

Dynamite is a mixture of nitroglycerine and some solid substance, which may be either inert or active. The solid substances commonly used are kieselguhr, wood-fiber, wood-pulp, charcoal and cork. The mixture is pressed into "sticks" about one inch in diameter and 8 inches in length and is then wrapped in paraffined paper. It is usually light brown in color. Dynamite freezes at 4° C. and is very insensitive to shock in the frozen state.

Explosive Gelatin, a mixture of colloided guncotton and nitroglycerine, is the most powerful explosive known, and at ordinary temperatures it is less sensitive to shock than dynamite. At low temperatures it is more sensitive than dynamite. It is a soft, gelatinous substance, yellowish brown in color and is prepared in the form of cartridges like dynamite.

Picric Acid Derivatives form the base of many common explosives, among which may be mentioned Mellinite (French), Lyddite (English) and Maximite. Picric acid is a crystalline substance possessing a very bitter taste. These explosives are generally used for charging shells, as they are not detonated when fired from a gun.

Mercury Fulminate, formed by treating metallic mercury with nitric acid and alcohol, is extensively used as an exploder with dynamite, guncotton, picric acid, etc. It is a gray crystalline substance of specific gravity 4.42. It is easily exploded by heat, an electric spark usually being employed.

[R. G. HUDSON.]

EXPONENTIAL FUNCTIONS. — (*See also Roots and Powers.*) When the relation between any variable y and another variable x is such that x occurs as an exponent of one or more terms, y is said to be an exponential function of x. Of particular importance in connection with electric circuits are the exponential functions ϵ^x and ϵ^{-x}, where ϵ is the base of the natural logarithms (*see Logarithms*).

ϵ^x may be obtained directly from the table of common logarithms (*see Logarithms*) from the relation that ϵ^x is equal to the number whose logarithm to the base 10 is $0.4343\,x$ (or more exactly $0.4342945\,x$), which may be written symbolically:

$$\epsilon^x = \log_{10}^{-1}(0.4343\,x).$$

Similarly,

$$\epsilon^{-x} = \frac{1}{\log_{10}^{-1}(0.4343\,x)}.$$

Example. — Find the value of ϵ^{10}. We have $0.4343 \times 10 = 4.343$, whence $\epsilon^{10} = 22{,}050$.

For convenience, however, the following table giving the value of ϵ^x and ϵ^{-x} from $x = 0$ to $x = 6$ is given. For larger values of x use the above relations. Also note that for $x < 0.1$ (*see Series*).

$$\epsilon^x = 1 + x \text{ with an error of less than 0.47 per cent,}$$

$$\epsilon^{-x} = 1 - x \text{ with an error of less than 0.54 per cent,}$$

$$\epsilon^x = 1 + x + \frac{x^2}{2} \text{ with an error of less than 0.016 per cent,}$$

$$\epsilon^{-x} = 1 - x + \frac{x^2}{2} \text{ with an error of less than 0.018 per cent.}$$

A more complete table is given in the *Smithsonian Mathematical Tables, Hyperbolic Functions* (*No. 1871*), by G. F. Becker and C. E. Van Orstrand, Washington, 1909. Semi-exponentials, i.e., values of $\frac{1}{2}\epsilon^x$ and $\log_{10} \frac{1}{2}\epsilon^x$, are given in *Tables of Complex Hyperbolic and Circular Functions*, by A. E. Kennelly, Cambridge, Mass., 1914.

[W. A. Del Mar.]

FACTORIALS. — The multiple product represented by

$$n(n-1)(n-2)\ldots 3 \times 2 \times 1$$

is called "*n* factorial," and is represented either by the symbol $n!$ or $\underline{n|}$. The following table gives the value of $n!$ up to $n = 10$.

1! =	1.	6! =	720.
2! =	2.	7! =	5040.
3! =	6.	8! =	40320.
4! =	24.	9! =	362880.
5! =	120.	10! =	3628800.

[W. A. Del Mar.]

FANS. — (*See also Blowers and Compressors; Draft, Mechanical.*) For ventilating and drying purposes and for producing mechanical draft, two kinds of fans are used, the disk fan and the centrifugal fan.

Disk Fans. — A windmill reversed, that is, driven by power applied to the shaft, may be used to blow air in large volume at low pressure, and it is then called a disk fan. Such fans are in common use for blowing air into or out of a room for the purpose of ventilation. Usually they consist simply of a rapidly rotating shaft carrying four or more nearly flat blades slightly inclined to the plane of rotation. Sometimes these blades are given various curved forms for the purpose of increasing the efficiency of the fan.

Centrifugal Fans. — The older form of centrifugal fan is that of a paddle wheel, a rotating shaft carrying from four to twelve radial arms, to which are attached flat blades in axial planes. In modified forms the blades are bent backward or forward, with reference to the direction of rotation, from an axial plane. Very large centrifugal fans up to 25 feet diameter and 10 feet width have been built for ventilation of mines, and in many cases without an external casing, but usually a spiral casing is used, with a tangential discharge outlet, with two "eyes," or circular inlets, concentric with the shaft, one on each side of the casing. In a recent modification of the centrifugal fan known as the "multivane" or "Sirocco" fan, the number of blades is increased to from 30 to 80; the blades or vanes are made relatively very long, axially, and narrow, radially, the ratio of length to width being as much as 9 to 1; they are made of curved form, the outer edge tipped forward in the direction of rotation and the diameter of the eyes in the casing and the radial distance of the vanes from the shaft are greatly increased. The pressure produced by centrifugal fans varies practically as the square of the speed of the tips of the blades and with the forms of the blades, and reaches a maximum commercially of about 1 pound per square inch for ordinary types of centrifugal or multivane fans. Much higher pressures have recently been obtained from special forms of fans built on the principles of steam turbines (*see Blowers and Compressors*).

POWER REQUIRED. — In the article on *Blowers and Compressors* is given the formula for "useful" work done by a blowing machine. Since an ordinary fan seldom produces a pressure of more than 1 per cent of normal atmospheric pressure, the change in the volume and static pressure of the air as it passes through a fan is negligibly small in comparison with the initial volume and pressure, and the formula for the theoretical horse power reduces to

$$P = \frac{1}{33,000}\left[\frac{dQ^3}{2\,g\,(60\,A)^2} + 144\,p_sQ\right],$$

where

p_s = the excess of static pressure at discharge over the initial static pressure, in pounds per square inch,

Q = cubic feet of air displaced per minute,

$d = \dfrac{1.33\,B}{460 + t}$ = weight of one cubic foot of air at the barometric pressure B (inches of mercury) and at $t°$ F.,

A = cross section of full outlet opening in square feet,

g = acceleration due to gravity in feet per second (= 32.2),

$p_v = \dfrac{d}{2 \times 144\,g}\left(\dfrac{Q}{60\,A}\right)^2$ = pressure in pounds per square inch necessary to give an average linear velocity $V_a = \dfrac{Q}{A}$ feet per minute to the air.

This pressure p_v is called the "velocity" pressure.

Useful or "Air Horse Power" of the fan may then be written

$$P = \frac{(p_v + p_s)\,Q}{229}.$$

The total pressure $p_v + p_s$ developed by the fan is called the "impact" or "dynamic" pressure. The pressures developed by a fan are usually expressed in inches of water column; hence putting H_v and H_s for the corresponding inches of water column required to balance p_v and p_s, the above formulas become

$$H_v = 0.832 \times 10^{-6} \frac{d\,Q^2}{A^2},$$

$$P = \frac{(H_v + H_s)\,Q}{6360}.$$

When the discharge outlet is restricted (e.g., by partially closing the discharge valve), the cross section A refers to the area of the discharge pipe between the restriction and the fan, not to the cross section of the restricted opening.

Actual Horse Power. — The actual horse power required to drive the fan is equal to the value given by the last formula divided by the efficiency. The fan efficiency depends not only upon the design of the fan, but also upon the relative values of the velocity and static pressures. The maximum efficiency of a centrifugal fan ranges from 40 to 70 per cent. The maximum efficiency of disk fans usually ranges from 30 to 40 per cent. The table below, taken from curves published by F. R. Still of the American Blower Co., in the *Jour. Wes. Soc. Eng.*, 1902, is fairly representative of the performance of ordinary steel-plate centrifugal fans. For a given type of fan and given ratio of velocity pressure within the casing on the outlet side to the static pressure, there is a fixed relation between the linear velocity $V_a = \frac{Q}{A}$ of the air within the casing on the outlet side and the peripheral velocity V_f of the fan; the ratio $\frac{V_a}{V_f}$, as calculated from Still's curves, is also given in the table below.

$\frac{H_v}{H_s}$	Efficiency	$\frac{V_a}{V_f}$	$\frac{H_v}{H_s}$	Efficiency	$\frac{V_a}{V_f}$
0.00	0.00	0.00	0.4	0.38	0.45
0.05	0.30	0.22	0.5	0.37	0.47
0.10	0.43	0.30	1.0	0.32	0.51
0.15	0.43	0.35	1.5	0.30	0.53
0.20	0.42	0.39	2.0	0.28	0.54
0.30	0.41	0.42	∞	0.22	0.58

More recent fans of the multivane or "Sirocco" type, when properly proportioned, have given efficiencies of 60 per cent and upwards.

THE VOLUME OF AIR DISCHARGED per minute is $Q = V_a A$ where V_a is the linear velocity of the air in feet per minute. When the speed is kept constant and the outlet pipe is partially closed, the linear velocity of the air through the full cross section A of the outlet decreases and the power required

to drive the fan decreases. A fan running at constant speed requires maximum power when the discharge outlet is wide open; the volume discharge is also a maximum under these conditions.

For an ordinary steel-plate fan running at a given speed the maximum volume of air per minute which it can deliver is roughly $\frac{1}{3}DWV_f = \frac{\pi}{3}D^2WN$, where D is the diameter of the fan in feet, W its width (at periphery) in feet, V_f the peripheral velocity of the fan in feet per minute and N the velocity in revolutions per minute.

The capacity of disk fans working against very low resistances is directly proportional to the area of the circle inclosing the fan and to the number of revolutions per minute, and varies with the form and inclination of the vanes. An ordinary type of propeller fan of diameter D feet will deliver $Q = KD^3N$ cubic feet per minute, where K ranges from 0.4 to 0.7 (depending on the design of the fan) when the resistance is small, the delivery decreasing rapidly as the resistance is increased.

DIMENSIONS AND SPEED.— The full discharge outlet A of an ordinary steel plate fan is usually about two-thirds the product of the width W by the diameter D of the fan, that is $A = \frac{2}{3}DW$. The width of the fan ranges from one-third to one-half the diameter. Using the latter figure, we have $D = \sqrt{3A}$. From this formula and the table given above a rough estimate of the dimensions of a fan for a given service may be made. For example, 20,000 cubic feet of air per minute at 60° F. is to be discharged against a static head of 1 inch of water; what must be the approximate dimensions and speed of the fan and what will be the approximate horse power required? The size of fan and the horse power required will depend upon the linear velocity of the air through the fan, the greater this velocity the smaller the fan and the greater the horse power. Using the symbols as defined above we have $Q = 20{,}000$, $H_s = 1$, $d = 0.0766$. A reasonable value of the linear velocity V_a is 2000 feet per minute. Then $A = 10$, $D = 5.48$, $W = 2.74$, $H_v = 0.255$, $\frac{H_v}{H_s} = 0.255$, $\frac{V_a}{V_f} = 0.41$, $V_f = 4880$, $N = 284$, efficiency $= 0.415$, H.P. $= 9.6$. That is, the diameter of the fan should be approximately 5 feet 6 inches, its width 2 feet 9 inches, its speed 285 r.p.m., and 9.6 horse power will be required to operate it. If V_a is taken as 4000 feet per minute, then the required diameter will be approximately 3 feet 10 inches, its width 1 foot 11 inches, its speed 650 r.p.m., and 20 horse power will be required to operate it.

The above method of arriving at the size of fan is extremely rough at best; for more accurate data the reader is referred to manufacturers' catalogues.

SPECIFICATIONS FOR FANS.*— The following memoranda are intended to assist in writing specifications. See also article on *Blowers* and article on *Specifications*.

General description of fan and service for which it is to be used. Rating, cubic feet of air per minute, under specified conditions of test. Whether exhaust or pressure. How supported. Whether fixed or oscillating. Details of motor, i.e., whether a-c. or d-c., frequency, phases and voltage.

MOTOR DRIVE.† — (*See also Motors, Industrial Applications of.*) The load on a fan motor increases as the speed rises and unless some sort of shuttering is provided the motor will be fully loaded when it comes up to speed. Shuttering is essential and the starting conditions should be carefully considered, when a synchronous motor is intended for driving the fan. As the torque

* By W. A. Del Mar. † By D. B. Rushmore.

required to start a fan is usually small, a motor with low-resistance starting winding may be used without requiring a very heavy current. To keep the current down, however, a low tap on the starting compensator must be used and an intermediate step may be very desirable.

Fig. 1 shows the starting-torque curve of a shuttered centrifugal fan from rest to full speed, and also a speed-torque and a speed-current curve of a synchronous motor with a squirrel-cage starting winding of fairly low resistance plotted for 50, 70 and 100 per cent of normal voltage. If the motor is started from the 50 per cent tap of the compensator it will bring the fan to about 80 per cent of full speed. If the motor is then thrown over to the full-line voltage it may exert an excessive torque, and the current, as shown by the current curve, will rise to a very high value. If an intermediate tap is provided — say a 70 per cent tap — the torque exerted will be less but still enough to bring the motor to about 95 per cent of synchronous speed and the current will be much less. Application of the field would then pull the machine into step after which it could be thrown over to the line with a very little rush of current. For a variable-speed service the synchronous motor is of course not suitable and a phase-wound induction motor must be used.

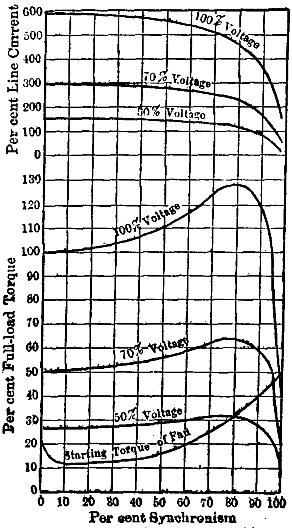

Fig. 1. Curves of Synchronous Motor with Low-resistance Starting Winding

For direct-current installations shunt motors are preferred, the speed adjustment being accomplished either by field control, armature control or a combination of the two. Field control is generally used where the motor operates for long intervals at speeds between 50 and 100 per cent of maximum speed; the combination control is used if the motor operates for long intervals at speeds between 75 and 100 per cent of maximum speed, and is occasionally required to operate at speeds below 75 per cent; and armature control is used advantageously for motors operating at long intervals near full speed, but where occasionally a lower speed is required. Ventilating fans offer one of the best applications for armature control because the torque and current decreases with the cube of the speed.

With very large mine fans, having a high inertia, the time required for acceleration is comparatively long — one minute or more — and this must be considered when the starting resistances are selected. Starting resistances for motors driving such large fans should therefore as a rule be of a larger size than would ordinarily be the case.

[Wm. Kent.]

FEED-WATER HEATERS AND PURIFIERS.—(*See also Boilers; Power Stations, Steam Electric.*) Impurities in the water supplied to a boiler may cause: (1) the formation of scale on the heating surface of the boiler, resulting in a decrease of boiler efficiency and overheating and consequent weakening of the tubes and plates; (2) the corrosion and consequent weakening of the tubes and plates; (3) an increase in the amount of suspended moisture carried over by the steam from boiler to engine. Sulphates of lime and magnesia, soluble salts of silica, iron and aluminum and suspended matter are the chief scale-forming impurities. Acids, organic matter, magnesium chloride and sulphate cause corrosion, while priming is induced by the presence of organic matter, sodium carbonate and other alkalies.

By the introduction into the feed water of various chemicals, as, for example, carbonate of soda, the scale-forming impurities may be changed into harmless substances by the reaction between the impurities and the "boiler compounds" introduced. Again, the adhesion of the scale to the heating surfaces may be prevented by the introduction into the feed water or boiler of such substances as kerosene oil. Suspended matter, such as sand, mud, insoluble organic matter, etc., may be eliminated by mechanical filtration or by allowing the water to stand in settling tanks. Organic impurities usually float on top of the water when the boiler is making steam and may be blown out through a "surface blow-out." Precipitated matter may be ejected by frequent blowing off before it has time to form a crust. Scale, when it has once formed, can be removed only by cleaning the tubes with some form of scraper. Very hard sulphate-of-lime scale may be softened so as to be more easily scraped, by dissolving a considerable quantity, say 50 to 100 pounds, of caustic soda in the boiler and slowly boiling it at atmospheric pressure for from 12 to 24 hours. Carbonates of lime and magnesia, two of the chief scale-forming impurities, may be almost completely precipitated by raising the temperature of the water to 290° F. (= boiling point for a pressure of about 60 pounds absolute).

SAVING DUE TO PREHEATING FEED WATER.—Although the heating and subsequent filtering or settling of the feed water results in the elimination of certain of the impurities, the primary object of preheating the feed water is to reduce the coal consumption. The heat required to raise the temperature of 1 pound of feed water 11° F. is approximately 1 per cent of the total heat required to convert the water into saturated steam at ordinary pressure. Hence, for every 11° F. the temperature of the feed water is raised by the application of heat which would otherwise be wasted, a saving of approximately 1 per cent will be effected in the amount of coal required. Let H = total heat of the steam at the given pressure, h_0 = heat of the water entering the heater, h = heat of the water leaving the heater, then the saving, expressed as a percentage of the heat that would be required by a boiler without a superheater, is

$$S = 100\frac{h-h_0}{H-h_0}.$$

The values of H, h and h_0 may be taken from steam tables (*see Steam*). This formula also gives the saving in fuel, provided the boiler efficiency is the same with or without the feed-water heater. However, if the boiler is overdriven, the installation of a feed-water heater will effect a greater saving than that given by the formula, since when the work to be done by the boiler is reduced the boiler efficiency will also increase.

TYPES OF FEED-WATER HEATERS.—The heat used for preheating the feed water may be derived: (1) from the exhaust steam; (2) from the flue

gases, in which case the heater is usually called a "fuel economizer"; (3) from live steam taken directly from the boilers, in which case the primary function of the heater is to purify the feed water, and it is therefore usually called a "live-steam purifier." The heat may be transmitted from the steam to the water either (1) by allowing the steam to mingle with the water and give up its heat by condensation, or (2) by passing the water and steam through separate chambers arranged so that the heat is conducted to the water through the walls of the chambers. These two types of heaters are referred to respectively as "open" and "closed" heaters. Closed heaters may be either of the water-tube or steam-tube type; in the former the steam surrounds a set of tubes through which the water is passed, while in the latter the steam is passed through a set of tubes surrounded by water. A closed heater in which the steam pressure is less than atmospheric is called a "vacuum" or "primary" heater; such heaters are frequently used in the exhaust of condensing engines. "Atmospheric" or "secondary" heaters are those in which the steam pressure is that corresponding to the back pressure of the engines or pumps. A heater in which the steam pressure is the same as that in the boiler is called a "pressure" heater.

Gebhardt gives the following list of typical heaters used in this country:

- Exhaust steam
  - Open — Atmospheric: Cochrane. Hoppes. Stillwell. Webster.
  - Closed { Atmospheric, Vacuum, or Pressure:
    - Wainwright, Wheeler — Water Tube.
    - Otis, Berryman — Steam Tube.
- Flue gas: Green. American. Sturtevant.
- Live steam — Open — Pressure: Hoppes. Baragwanath.

Open Heaters. — The essential parts of an open heater are: (1) a shell containing (2) a set of trays or pans to catch the scale-forming elements precipitated from the water; (3) a filter to take out suspended impurities; and (4) an oil separator to extract the oil from the steam before it enters the superheater.

Dimensions. — C. L. Hubbard (*Practical Engineer, Jan. 1, 1909*) gives the following:

Exhaust heaters should be proportioned according to the quality of the water to be used, the size being increased with the amount of mud or scale-producing properties which the water contains, regardless of the quantity of water to be heated. The general proportions of an open heater will depend somewhat upon the arrangement of the trays or pans, but an approximation of the size of shell for a cylindrical heater is as follows: $A = H \div aL$; $L = H \div aA$; in which A = sectional area of shell in square feet; L = length of shell in linear feet; H = total weight of water to be heated per hour divided by the weight of steam used per horse power per hour by the engine; a = 2.15 for very muddy water, 6.0 for slightly muddy water, and 8.0 for clear water.

The pan or tray surface varies according to the quality of the water, both as regards the amount of mud and the scale-making ingredients. The surface

in square feet for each 1000 pounds of water heated per hour may be taken as follows, for the vertical and horizontal types respectively:

Very bad water	8.5 and 9.1
Medium muddy water	6 and 6.5
Clear and little scale	2 and 2.2

The space between the pans is made not less than 0.1 of the width for rectangular and 0.25 of the diameter for round pans. Under ordinary circumstances it is not customary to use more than six pans in a tier, in order to obtain a low velocity over each pan. The size of the storage or settling chamber in the horizontal type varies from 0.25 to 0.4 of the volume of the shell, depending on the quality of the water; 0.33 is about the average. In the case of vertical heaters, this varies from 0.4 to 0.6 of the volume of the shell. Filters occupy from 10 to 15 per cent of the volume of the shell in the horizontal type and from 15 to 20 per cent in the vertical.

Temperature Elevation of Feed Water. — Let H = total heat of steam in B.t.u. above 32° F. at the pressure of the steam in the heater; I = initial temperature of the water entering the heater; F = final temperature of the water leaving the heater; K = ratio of weight of exhaust steam condensed per hour in the heater to weight of the feed water per hour; then, neglecting loss due to radiation,

$$F = \frac{I + K(H + 32)}{1 + K}.$$

Closed Heaters. — (*H. L. Hepburn, Power, April, 1902.*) Let W = pounds feed water per hour; A = sq. ft. of heating surface between steam and water; T_s = temperature of the steam; I = initial temperature of the water; F = final temperature of the water; U = B.t.u. transmitted per sq. ft. per hr. per deg. difference of temperature between the steam and the water; then

$$A = \frac{2.30\,W}{U} \log_{10} \frac{T_s - I}{T_s - F}.$$

The value of U varies widely according to the condition of the surface and with the velocity of the water, and also depends upon whether the heater is of the water-tube or steam-tube type. Gebhardt gives the following values of U: for multi-flow water-tube heaters, 250 for plain copper or brass tubes and 300 for corrugated tubes with a water velocity of 50 feet per minute; for single-flow water-tube heaters, 175 for plain brass with a water velocity of 12.5 feet per minute; for coil water-tube heaters, 300 for copper tubes with a water velocity of 150 feet per minute; for steam-tube heaters, 120 for iron tubes.

Economizers. — Economizers for boiler plants are usually made of vertical cast-iron tubes contained in a long rectangular chamber of brickwork. The feed water enters the bank of tubes at one end, while the hot gases enter the chamber at the other end and travel in the opposite direction to the water. The tubes are made of cast iron because it is more non-corrosive than wrought iron or steel when exposed to gases of combustion at low temperatures. An automatic scraping device is usually provided for the purpose of removing dust from the outer surface of the tubes.

The amount of saving of fuel that may be made by an economizer varies greatly according to the conditions of operation. With a given quantity of chimney gases to be passed through it, its economy will be greater (1) the higher the temperature of these gases; (2) the lower the temperature of the water fed into it; and (3) the greater the amount of its heating surface.

The maximum saving of fuel which may be made by the use of an economizer when attached to boilers that are working with reasonable economy is about 15 per cent. If the boilers are not working with fair economy on account of being overdriven, then the saving made by the addition of an economizer may be much greater.

Temperature Elevation of Feed Water. — Let A = square feet of economizer heating surface per boiler horse power, T_1 = temperature (Fahrenheit) of flue gases entering economizer (ranges from about 450 to 700° F.); I = temperature of feed water entering economizer; F = temperature of feed water leaving economizer; W = pounds feed water per boiler horse power per hour; G = pounds flue gas per pound coal; C = pounds coal per boiler horse-power hour; S = specific heat of flue gases; U = B.t.u. transmitted per sq. ft. per hr. per deg. difference of temperature between flue gas and water; then

$$F - I = \frac{A\,(T_1 - I)}{\dfrac{W}{U} + \dfrac{(W + CGS)\,A}{2\,CGS}}.$$

A varies from 3.5 to 5, and U from 2.25 to 3.3, depending upon the conditions of operation. Putting $W = 30$, $S = 0.2$ and $U = 3.3$, the above formula reduces to

$$F - I = \frac{A\,(T_1 - I)}{9.1 + \dfrac{(5\,W + GC)\,A}{2\,GC}},$$

which is the formula advocated by the Green Economizer Co.

Rating and Cost. — Economizers are sometimes rated by tubes, the usual area per tube being 15 square feet. From 3.5 to 5 square feet are usually installed per boiler horse power. Economizers cost approximately $1.25 per square foot of heating surface, this figure including erection and brick setting.

[WM. KENT.]

FIRE-ALARM TELEGRAPH. — (*See also Telegraph Instruments and Apparatus; Telegraph Systems; Wiring of Buildings for Miscellaneous Devices.*) The object of fire-alarm telegraph systems is to notify the fire-fighting forces of a community promptly of the existence and location of a fire, and also to afford a means of communication between the various branches of the fire-fighting organization whether at a fire or in quarters.

The simplest form of fire-alarm system is shown in Fig. 1, where several fire alarm boxes are arranged in series in the alarm or "box" circuit extending from the fire-alarm headquarters throughout the district covered by the boxes. These boxes are provided with a clockwork mechanism, so that when the box is started or "pulled" by the person sending the alarm, a break wheel, carrying notches

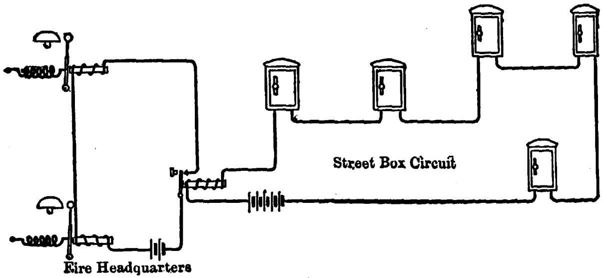

Fig. 1. Fire-Alarm System

corresponding to the code number of the box, is caused to revolve, thus making and breaking the circuit in accordance with the code. These makes and breaks cause the operation of the relay at headquarters and by means of a local circuit the gong sounds the alarm at headquarters. As many gongs as may be desired may be operated by the same relay, these being placed in the engine-house, men's quarters, or wherever else it is desired to give the alarm.

Types of Boxes. — The placing of a number of boxes on the same circuit gives rise to the possibility of confusion, due to two or more boxes being pulled at once. This is called "interference." A box which makes no provision against this confusion is called an "interfering box." A common type of box, termed the "non-interfering box," is so arranged that if two or more boxes on the same circuit are pulled at once the signal of the first box to be started will be transmitted without interference from the others, but the signals of the others will not be transmitted. In a later development, and one that is largely used, the arrangement is such that if any number of boxes up to four on the same circuit are simultaneously pulled, no interference and no loss of signals will be entailed, each box securing possession of the line in succession, the deferred boxes waiting their turn, so that the signals of all the boxes will be transmitted without confusion. These are called "non-interference succession boxes."

Gong Circuits. — In fire departments which have a number of engine and other apparatus houses, it is customary to establish a single fire-alarm headquarters, at which all box circuits center. From this headquarters other circuits, termed "gong circuits," extend to the apparatus houses. An alarm received over a box circuit may be transmitted to the gong circuits either manually or automatically.

Manual Systems. — In manual systems the box alarm is received at headquarters and then is set up on a transmitter, which, when started, automatically repeats the alarm over the desired gong circuits. The manual part of this operation may consist in placing a disc, notched on its periphery to accord with the desired box number, in the transmitter, and then starting the mechanism, the notches on the disc effecting the desired makes and breaks in the gong circuits. This method is employed in the fire-alarm system of the Borough of Manhattan, New York.

Another manual method of transmission is to set up the desired box number on a dial transmitter, which, when set in motion, transmits the alarm to the gong circuits. Still another method is to actually re-transmit the box numbers manually by means of a Morse key.

Automatic Systems. — In these the relays at headquarters, which are operated by the box circuits, automatically perform the making and breaking of the gong circuits, and thus re-transmit the box alarm to the gong circuits. This is advantageous in point of time saving, but has certain objectionable features in removing all discretionary power from the operators at headquarters.

Confusion in Fire-alarm Nomenclature. — Considerable confusion exists in the nomenclature of the fire-alarm art in various parts of the country. For instance, the term "automatic system," instead of applying to the automatic re-transmission of the alarm at fire headquarters, is frequently applied to those systems where the original alarm is automatically sent, as by the operation of a thermostat in a building under the influence of undue heat.

[S. G. McMeen.]

FLUXMETER. — (*See also Galvanometers.*) The Grassot fluxmeter is essentially a dead-beat galvanometer, the suspension fiber of which is designed to exert no appreciable torsional force on the moving system when the latter is displaced.

Construction. — Fig. 1 is a diagram showing its construction. The coil *C* swings in the uniform air gap between the pole pieces *NS* of a permanent magnet and the soft iron core *A*. The system is supported at the top by a single cocoon fiber, the upper end of this fiber being attached to a flat spiral spring *R*, to minimize the effect of shocks. The torsional force exerted by such a fiber is extremely small. *S* and S_1 are very thin silver strips, serving to lead the current to and from the coil *C*. These strips are in the form of springs, which, however, are extremely weak and therefore exert but a small theoretically inappreciable torsional force on the coil. An index or pointer is attached to the instrument, this pointer swinging over a calibrated scale. The fluxmeter is also provided with a mirror in addition to the pointer so that it may be used in conjunction with a lamp and scale or with a telescope and scale.

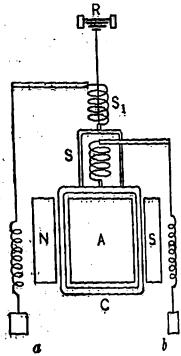

Fig. 1. Grassot Fluxmeter System

Principle of Operation. — When a given quantity of electricity is discharged through the moving coil, for example by changing the flux threading an exploring coil connected to the terminals *a* and *b*, a force is exerted upon the coil tending to deflect it. The only opposing forces (neglecting the small and theoretically inappreciable torsional forces) are the mechanical friction to motion and the back e.m.f. induced in the coil due to its motion through the field of the permanent magnet. The latter is proportional at any instant to the velocity of the coil, and the frictional force is also approximately proportional to this velocity. If both forces are directly proportional to the velocity, when a given quantity of electricity is discharged through the circuit, the coil comes to rest at a definite point, depending only upon its initial or "zero" position and the total quantity discharged through it. As the quantity of electricity discharged through an exploring coil, when the magnetic flux threading it is changed, depends solely upon the change in flux and the resistance of the coil and the rest of the circuit in series with it, the instrument may be calibrated to read directly the change in the flux density produced in the region occupied by the coil. In practice the friction is not exactly proportional to the velocity and the fiber and leading in springs usually exert an appreciable force on the coil. The instrument therefore has not proved altogether satisfactory.

Applications. — In motor or in dynamo work an exploring coil, consisting of one or more turns of wire, may be fixed or wound in position and the change in flux of induction observed on exciting the field magnet. Even in the largest work, where some minutes may be taken to reach the limit of magnetization, no error is thus introduced. The fluxmeter can also be used for the measurement of magnetic field strength, pole strength and the distribution of magnetism in bar magnets. It is also adapted to the measurement of permeability (q.v.) and hysteresis (q.v.).

Cost. — A direct reading fluxmeter with one exploring coil costs about $75. Additional exploring coils cost from $8 to $10 each.

FLYWHEELS FOR LOAD EQUALIZATION. — (*See also Hoists; Motors, Industrial Application of; Steel Mills, Electric Drive of.*) There are two methods in general use for equalizing a fluctuating load, the storage battery and the flywheel. The former is mostly used in connection with a central service where the peaks are of considerable duration and for which service the flywheel is entirely unsuitable. For short fluctuating loads, such as steel-mill service, mine hoists, etc., the flywheel is particularly suitable, and it may be applied either to the driving motor direct or to an intermediate motor-generator equalizing set, depending on the operating conditions.

Selection of Flywheel. — The problem of selecting a flywheel for a given service is not an easy one, and each case must be treated separately. The general problem is to determine what effect a flywheel will have on smoothing out the load fluctuations; what effect it will have on the motor and supply system; whether a flywheel is warranted; and what size flywheel will result in maximum economy.

Flywheel Effect. — The effectiveness of a flywheel, rotating at a given number of revolutions per minute, in equalizing the load, depends not only upon its weight but also upon the square of its radius of gyration (q.v.). The product of the weight of a flywheel by the square of its radius of gyration is commonly called the "flywheel effect"; it is proportional to the moment of inertia of the flywheel. A factor which limits the usefulness of a given flywheel is the allowable variation in speed, as the energy which a flywheel is able to give up is proportional to the difference between the squares of the initial and final speeds. Another point to be considered is the fact that a flywheel is not an inexhaustible source of energy. The time during which it can supply a certain number of horse-power is limited, and it can, with a given drop of speed, only supply a given number of horse-power seconds. A certain flywheel, for example, may easily take care of a peak amounting to 100 per cent overload for one second, but it may be entirely inadequate to handle a 50 per cent overload lasting for five seconds.

Induction Motor with Flywheel. — Let the motor at any instant be developing a torque T, and let the opposing torque of the load at this instant be T_1. Then $T = T_1 + \frac{I}{32.2}\frac{dw}{dt}$, where I is the moment of inertia of all the revolving parts and w their angular velocity. In the case of an induction motor the torque T is practically proportional to the slip (*see Motors, Induction*). By making use of this relation and the above equation the following working formula is readily deduced for the change in the torque developed by an induction motor for an interval during which the opposing torque of the load remains constant. Let

T_0 = torque, in pound-feet, developed by motor at a given instant.
T = torque, in pound-feet, developed by motor *t seconds later.*
T_1 = opposing torque, in pound-feet, due to the load, *assumed constant.*
R = ratio of torque (in pound-feet) to slip for the given motor, obtained from characteristic curves of the motor.
N = synchronous speed of motor, in r.p.m.
k = radius of gyration of flywheel, in feet (the inertia of the other rotating parts is usually negligible in comparison with that of flywheel).
W = weight of flywheel in pounds.

Calculate the constant

$$A = \frac{308\,R}{k^2WN}.$$

Then the torque developed by the motor t seconds from the time that its torque was T_0 is

$$T = T_1 - \frac{T_1 - T_0}{\epsilon^{At}},$$

where ϵ is the base of the natural system of logarithms (*see Exponential Functions*).

This equation shows that if the load torque suddenly increases from the value T_0 to a new constant value T_1, then the torque developed by the motor does not change immediately to T_1, but builds up to this value at a rate depending upon the value of the constant A. The smaller A the more slowly does the torque of the motor change; if A is sufficiently small and the load represented by the torque T_1 is of short duration, then the torque of the motor may increase only a relatively small amount before the load drops back to its original value. The constant A can be made small: (1) by having a flywheel with a large flywheel effect; (2) by using a high-speed motor, or (3) by designing the motor so that for a given torque the slip is large, i.e., with high secondary resistance.

[D. B. RUSHMORE, assisted by E. A. LOF.]

FREQUENCY INDICATORS. — (*See also Ammeters; Voltmeters; Wattmeters.*) The frequency of the current supplied by a generator may be determined directly from its speed, N revolutions per minute, and number of poles p, from the formula

$$f = \frac{Np}{120}.$$

The same formula also applies to a synchronous motor, N and p being the speed and number of poles of the motor. The speed may be measured by a revolution counter and stop watch or by means of a tachometer, or speed indicator. The latter may be calibrated to read the frequency directly for a given generator or motor.

INDICATING FREQUENCY METERS. — Indicating frequency meters are made in a variety of types, the most common being (1) the moving-vane or moving-coil type, (2) the induction type, and (3) those operating on the principle of the mechanical resonance of an iron reed acted upon by the magnetic field produced by a current from the given source.

Moving-vane Type of Frequency Indicator. — A common form of frequency indicator of this type consists of a moving vane, with pointer attached, so mounted that it is acted upon by two coils set at right angles to each other. One coil is connected in series with a non-inductive resistance and the other in series with a comparatively large inductance. The vane tends to set itself in the direction of the resultant field due to the currents in two coils, there being no controlling spring, and consequently for a fixed ratio of these currents the disc takes up a definite position irrespective of the values of these currents. The two circuits are so connected to the source of supply that when the voltage across the mains varies, the voltages across the two circuits of the instrument vary proportionally to each other, and therefore the position of the vane and pointer is unaffected by voltage variations. An increase in the frequency, however, decreases the current through the inductive circuit relative to that through the non-inductive circuit, and consequently causes a deflection of the vane and pointer; similarly a decrease in the frequency increases the current through the inductive circuit, producing a deflection in the opposite direction. The resistance and inductance of each circuit is so adjusted that for the standard frequency, e.g., 60 cycles, the pointer stands in the middle of the scale. A given instrument is suitable for a range ot frequency, from about 33 per cent below to 50 per cent above normal.

Effect of Wave Form. — Such instruments are affected to a very small extent by the wave form of the voltage on the mains to which they are connected. Numerous expedients have been devised to overcome this error by various combinations of resistive and inductive circuits, and by providing a small adjustable resistance in series with the inductance, this resistance being set to correspond with the wave form on which the instrument is to be used.

Moving-coil Type of Frequency Indicator.— This type is similar to the moving-vane type except that two moving coils, rigidly fastened together, constitute the moving element and the stationary element is a single coil.

Resonant-Circuit Frequency Indicator. — A new form of instrument of this type, in which the sensitiveness is greatly increased, has recently been developed (*Pratt and Price, Trans. A.I.E.E., 1912, Vol. 31, p. 1595*). The two moving coils or armatures are connected in series with suitable resistances, inductances and condensers, so adjusted that the two circuits are nearly in electrical resonance (*see Alternating Currents*) with the impressed frequency. A 6-inch deflection of the pointer over the scale of the

instrument is readily obtained for a change of frequency from 55 to 65 cycles per second, and by changing the constants of the circuits a 6-inch deflection can also be obtained for a change of frequency from 60 to 61 cycles per second. This instrument shows only a trace of variation due to wave form, voltage or temperature.

Induction-type Frequency Indicator. — In these instruments a disk is subjected to torque in opposite directions by two small shaded pole motors, the construction being similar to that of an induction voltmeter. The circuit of one motor is inductive and in the other is practical non-inductive. The disk or rotating member is provided with one edge not concentric, or some equivalent device is used, so that the torque developed on the disk varies with its position relative to the motor elements. The disk then finds a position in which the torques are balanced, which position will depend on the relative currents in the two motor elements. The current in the inductive element depends upon the frequency as in the types described above, and consequently the deflection of the disk is a measure of the frequency.

Vibrating-reed Type of Frequency Indicator. — In these instruments a series of vibrating reeds is provided, each tuned to vibrate at a frequency corresponding to a certain number of cycles per second, or sometimes the tuning is done for differences as small as ¼ cycle per second or less. Some arrangement is provided by means of which the frequency of the alternating circuit is communicated to these vibrating reeds. In one arrangement all of the reeds are mounted on a common support which is vibrated by a single electromagnet through which the alternating current whose frequency is to be measured passes. In another arrangement the reeds are attached to a rigid support but are constructed of magnetic materials and acted on by one or more electromagnets directly. These instruments are quite accurate in service if the voltage is not varied beyond that for which the instruments are intended, in which case the wrong reed may be made responsive.

COST OF FREQUENCY INDICATORS. — Switchboard frequency meters of the moving-vane or moving-coil type (not tuned), cost from $45 to $65. The tuned, or electrical resonance, switchboard type cost from $75 to $85. Vibrating-reed frequency indicators for switchboard service cost from $35 to $95; portable indicators of this type cost from $110 to $125; duty included in both cases. The various types are made for standard frequencies of 25, 40 and 60 cycles per second and for circuits of 110 or 220 volts. For higher voltages potential transformers should be used.

BIBLIOGRAPHY. — Jansky, C. M., *Electrical Meters*, N. Y., 1913; Pratt and Rice, *Resonant Circuit Frequency Indicator*, Trans. A.I.E.E., 1912, Vol. 31, p. 1595; Bulletins of Manufacturers.

[L. T. ROBINSON.]

FRICTION. — (*See also Automobiles, Electric; Bearings; Belts and Belting; Brakes and Braking Systems; Friction Drive; Gears and Gearing; Hydraulics, Principles of; Lubricants and Lubrication; Pipes and Piping; Railways, Energy Requirements for; Ropes and Rope Drive; Valves; also under name of machine in question.*) Friction is the tangential force set up whenever an external force is applied to a body tending to move it, or actually moving it, over the surface of another. There are two distinct types of friction, namely, "sliding friction" and "rolling friction." Again, the force required to start a body sliding or rolling over the surface of another body (in addition to the force required to overcome the inertia of the first body) is in general greater than the force required to keep it sliding or rolling at slow speed after it is once started. The force required to start a body is called the "static friction" or the "friction of rest" and the force required to keep it in motion is called the "kinetic friction" or the "friction of motion." There is evidence to indicate that there is no abrupt change in the value of the friction from rest to motion, but that the change is a continuous one, varying rapidly with the speed at low speeds. At first the friction decreases with the speed, at moderate speeds it is nearly constant, and at higher speeds increases rapidly with the speed. Air friction must also be taken into account at very high speeds.

COEFFICIENT OF SLIDING FRICTION (f) AND ANGLE OF REPOSE (θ). — The coefficient of sliding friction is defined as the ratio of the force required to move a body along a horizontal plane surface to the normal component of the force pressing the body against this surface. If the body is resting on an inclined plane and the force normal to this plane is due only to the weight of the body, the angle of inclination of this plane to the horizontal required to start the body is called the angle of repose. The tangent of this angle is equal to the coefficient of static friction, i.e.,

$$f = \tan \theta.$$

The friction of a bearing is a special case of sliding friction (*see Bearings*).

Factors Affecting the Coefficient of Sliding Friction. — For a given normal pressure (force per unit area perpendicular to surface of contact) the coefficient of friction is approximately independent of the area of contact, all other conditions being the same, except in the case of fibrous materials, in which case the coefficient increases with extent of surface.

The coefficient of friction, however, is as a rule materially affected by the pressure, speed, degree of smoothness of the surfaces in contact, the condition of these surfaces (whether dry, moist, greasy or oily), temperature in case of lubricated surfaces, etc.

Friction of Fluids Against Solids. — Thurston states that for all fluids, whether liquid or gaseous, the resistance is: (1) independent of the pressure between the masses in contact; (2) directly proportional to the area of rubbing-surface; (3) proportional to the square of the relative velocity at moderate and high speeds, and to the velocity nearly at low speeds; (4) independent of the nature of the surfaces of the solid against which the stream may flow, but dependent to some extent upon their degree of roughness; (5) proportional to the density of the fluid, and related in some way to its viscosity (*see Pipes and Piping; Hydraulics, Principles of*).

Friction of Lubricated Surfaces approximates more closely the laws of fluid friction the more thoroughly the surface is lubricated (*see also Bearings; Lubricants and Lubrication*).

Values of the Coefficient of Sliding Friction. — Due to the numerous factors which affect the coefficient of friction, the values of this coefficient given

by various authorities are found to differ widely. The table below will serve to indicate the order of magnitude of the coefficient in the cases stated, but it should be kept in mind that these values are only rough approximations (*see also Belts and Belting, Brakes and Braking Systems; Ropes and Rope Drive*).

COEFFICIENT OF STATIC FRICTION BETWEEN DRY, SMOOTH SURFACES

Materials	Pressure, lb. per sq. in.	*f*	Authority
Wrought iron on wrought iron	187–560	0.25–0.41	Rennie.
Wrought iron on cast iron	187–672	0.28–0.38	Rennie.
Steel on cast iron	187–672	0.30–0.40	Rennie.
Brass on cast iron	187–784	0.21–0.23	Rennie.
Yellow pine on yellow pine	100–1500	0.25–0.32	Messiter and Hanson.
Spruce on spruce	100–800	0.18–0.53	Messiter and Hanson.
Metals on metals	....	0.15–0.25	Rankine.

COEFFICIENT OF STATIC FRICTION AND ANGLES OF REPOSE OF BUILDING MATERIALS

Materials	Angle of repose, degrees	*f*	Authority
Dry masonry and brickwork	31–35	0.6–0.7	Rankine.
Masonry and brickwork with damp mortar	36.5	0.74	"
Masonry on dry clay	27	0.51	"
Masonry on moist clay	18.25	0.33	"
Timber on stone	22	0.4	"
Timber on timber	11.3–26.5	0.2–0.5	"
Timber on metals	11.3–31	0.2–0.6	"
Iron on stone	16.7–35	0.3–0.7	"
Earth on earth	14–45	0.25–1.0	"

COEFFICIENT OF KINETIC FRICTION (*Rankine*)

Materials	Dry surface	Wet surface	Soapy surface	Oily or greasy surface
Wood on wood	0.25–0.5	....	0.04–0.2	....
Metals on oak	0.5–0.6	0.24–0.26	0.2	....
Metals on elm	0.2–0.25	....	....	....

Hemp on oak	0.53	0.33	....	....
Leather on oak	0.27–0.38	....	....	....
Leather on metals	0.56	0.36	0.15–0.23	....
Bronze on lignum vitæ	....	0.05	....	....

Power Lost Due to Sliding Friction. — Let

f = coefficient of friction,
W = total force acting normal to surface of contact,
v = velocity in feet per second,

then the power lost is

$$fWv \text{ foot-pounds per second} = \frac{fWv}{550} \text{ h.p.}$$

COEFFICIENT OF ROLLING FRICTION. — Let

F = resisting force in pounds tangent to circumference of wheel,
r = radius of wheel in feet,
W = load on wheel in pounds,

then the coefficient of rolling friction (f) is defined by the relation

$$F = \frac{fW}{r}.$$

Note that the value of f depends upon the unit in which r is expressed. If r is expressed in inches instead of feet f will be 12 times as great.

Factors Affecting the Coefficient of Rolling Friction. — Rolling friction is a consequence of the irregularities of form and the roughness of surface of bodies rolling one over the other. Its laws are not yet definitely established in consequence of the uncertainty which exists in experiment as to how much of the resistance is due to roughness of surface, how much to original and permanent irregularity of form, and how much to distortion under the load. (*Thurston.*)

Values of Rolling Friction. — The following are some reported values of rolling friction, when r is expressed in feet,

Lignum-vitæ roller on oak track	0.0016
Elm roller on oak track	0.0027
Car wheel on iron or steel rail	0.0015–0.002
Steel-tired wagon wheel on soft soil	0.065
Steel-tired wagon wheel on smooth hard road	0.02
Steel-tired wagon wheel on wood	0.0185
Steel-tired wagon wheel on asphalt	0.012

Power Lost Due to Rolling Friction. — Let

f = coefficient of friction, in feet,
W = total vertical load on wheel, in pounds,
r = radius of wheel, in feet,
n = number of revolutions of wheel per second,
v = linear speed in feet per second,

then the power lost in friction is

$$\frac{fWv}{r} = 6.28\, fWn \text{ foot-pounds per second}$$

$$= \frac{fWv}{550\, r} = \frac{fWn}{87.5} \text{ h.p.}$$

[H. PENDER AND R. G. HUDSON.]

FRICTION DRIVE. — (*Adapted from paper by W. F. M. Goss, Trans. A.S.M.E., 1907.*) A friction drive consists of a fibrous or somewhat yielding driving wheel working in rolling contact with a metallic driven wheel. Such a drive may consist of a pair of plain cylinder wheels mounted upon parallel shafts, or a pair of beveled wheels, or of any other arrangement which will serve in the transmission of motion by rolling contact.

Suitable fibrous materials for the driving wheel are straw fiber, leather fiber, tarred fiber, sulphite fiber, or leather; suitable materials for the driven wheel are iron, aluminum and type metal.

Crushing Strength and Safe Load for Fiber Wheels. — The crushing strength of each fibrous material, as determined by finding the load under which the wheel failed before 15,000 revolutions had been made, is given in the following table, together with the safe working load, taken as one-third the crushing load.

Material	Crushing load, lb. per in. width	Safe load, lb. per in. width
Straw fiber........	750	250
Leather fiber......	1200	400
Tarred fiber.......	1200	400
Sulphite fiber......	700	233
Leather...........	750	250

Coefficient of Friction. — The coefficients of friction between the various fibrous materials and the three metals are given in the table below, these being maximum values, corresponding to a slip of about 2 per cent. The friction at constant slip was found to be practically independent of the pressure between the limits of 150 and 400 pounds per inch width of face in contact.

Horse-power Transmitted. — Goss gives the following formula for the maximum horse-power which can be safely transmitted by a friction drive

$$P = \frac{\pi d}{12} \times \frac{WPN \times 0.6 f}{33{,}000} = kdWN,$$

in which d = diameter of driving wheel in inches, W = width of face in inches, P = safe working pressure in pounds per inch of width, N = revolutions per minute, f = coefficient of friction, 0.6 a factor for the decrease of the coefficient in service and for the loss in journal friction, k a coefficient including P, f and the numerical constants.

COEFFICIENTS OF FRICTION AND HORSE-POWER OF FRICTION DRIVES

Surface of Driving Pulley	On iron		On aluminum		On type metal	
	f	k	f	k	f	k
Straw fiber..........	0.255	0.00030	0.273	0.00033	0.186	0.00022
Leather fiber.........	0.309	0.00059	0.297	0.00057	0.183	0.00035
Tarred fiber..........	0.150	0.00029	0.183	0.00035	0.165	0.00031

FUELS.—(*See also Boilers; Calorimeters, Fuel; Gas; Gas Producers; Power Stations.*) Commercial fuels are wood, peat, coal, charcoal, coke, petroleum and gas. These fuels in the raw state all contain carbon and hydrogen as the heat-producing elements, together with oxygen, nitrogen, sulphur, earthy matter and moisture, which are undesirable and detract from the value of the fuel. Sulphur in the form of sulphide of iron, which frequently exists in coal, tends to cause spontaneous combustion.

Wood is rarely used for the production of large amounts of energy. Peat, which is formed in bogs or marshes by the partial decomposition or destructive distillation of vegetable materials, is unsuitable for fuel until dried. To compete with coal, it must also be especially prepared and compressed into briquettes; such briquettes are extensively used in Europe, but up to the present peat has not been employed commercially in this country. Charcoal is the solid material left after evaporating the major portion of the volatile ingredients of wood or peat, or other vegetable matter. Coke is similarly the solid material left after evaporating the volatile ingredients of coal. Coke is of dark gray color, with slightly metallic luster, porous, brittle and hard. It is hygroscopic, i.e., absorbs and retains moisture when exposed to the air. One pound of coal yields from 0.35 to 0.90 pound of dry coke, depending on the kind of coal from which it is made. Coke is used chiefly in blast furnaces and foundries; its high cost prevents its use for the production of power.

In power plants, the fuels used are coal, oil and gas. Coal and oil will be treated in detail below; for a discussion of gas see the article on *Gas*.

DEFINITIONS.—When a fuel is heated to red heat in a non-oxidizing atmosphere, the carbon in the solid residue is called "fixed carbon." The hydrocarbons and other gaseous compounds which distil off are called "volatile matter." When a fuel burns or oxidizes, the solid mineral matter left is the ash. Fuels in the raw state also contain a certain amount of water or "moisture." The fixed carbon and volatile matter together are called the "combustible" though the nitrogen and oxygen in the volatile matter are not actually combustible. The determination of the fixed carbon, volatile matter, moisture and ash in a fuel is called the "proximate analysis." The determination of the moisture and ash of the fuel and the constituent elements of the combustible, i.e., the carbon, hydrogen, oxygen, nitrogen and sulphur, is called the "ultimate analysis." The "heating" or "calorific" value of a fuel is the number of units of heat energy developed as the result of the complete combustion of a unit weight (or mass) of the fuel. In this country and in England, the heat energy is expressed in British thermal units, abbreviated B.t.u. (1 B.t.u. = 777.5 ft.-lb. = 0.2928 watt-hour = 0.3927×10^{-4} hp.-hr.) and the unit of weight is 1 pound. The heating or calorific value should be expressed as so many B.t.u. per pound of *combustible*, although it is sometimes given in B.t.u. per pound of *dry fuel* or per pound of *fuel as fired* (including ash and moisture).

MOISTURE IN FUELS.—The analyses of the solid fuels given above are of perfectly dried fuels. Wood when freshly felled contains on an average about 40 per cent of moisture, varying with different species. After eight to twelve months drying in the open air, the moisture is reduced to 20 or 25 per cent. If dried in an oven to greater dryness, it will, on exposure to the atmosphere, absorb moisture again, and the percentage it will then contain will vary with the dryness or dampness of the air; that is, wood is hygroscopic.

The moisture in coal may be surface moisture, received from rain while being transported or in storage, and which may be dried out on exposure to the atmosphere, or hygroscopic moisture, contained inside of the lumps, which cannot be

dried out without subjecting the coal for some time to a temperature considerably above 212° F. The anthracite, the semi-bituminous coals and the bituminous coals of the Appalachian coal field seldom contain hygroscopic moisture in excess of 1 or 2 per cent, but it is a characteristic of the western bituminous coals and lignites that the hygroscopic moisture is much higher; thus in some Illinois coals it is as high as 14 per cent. When this moisture is dried out, the coal will again absorb it on being exposed to the atmosphere. Some lignites contain as much as 30 per cent moisture.

ULTIMATE ANALYSES OF VARIOUS FUELS. — Typical ultimate analyses of various fuels together with the percentage of ash are given below; the analyses are for fuels from which all moisture has been expelled.

	C	H	O	N	S	Ash
Wood	50	6	41	1	..	2
Peat	59	6	30	1	..	4
Lignite	69	5	16	1	1	8
Bituminous coal	76	5	10	1	1	7
Semi-bituminous coal	86.5	4.5	3	1	0.5	4.5
Semi-anthracite	78.5	3.5	2	1	2	12
Anthracite	77	2.5	2	1	1	16.5
Charcoal	82	2	..	1	..	15
Coke	89	..	..	..	1	10
Petroleum (Texas)	84.5	11	3	..	1.5	..
Natural gas	70	25	1	4	..	..

In the progression from wood to anthracite, the chief change in chemical constitution, as shown in the above table, is a decrease in the oxygen from 41 per cent to 2 per cent. The hydrogen also decreases, but less rapidly. In all the varieties of coal, the ash is exceedingly variable, ranging from as low as 2 per cent up to 25 per cent or more. Coals high in ash are usually also high in sulphur. The ash and sulphur may be removed to a considerable extent by crushing and washing.

AIR REQUIRED FOR COMBUSTION. — The theoretical weight of air A required for complete combustion of 1 lb. of fuel may be determined from the formula,

$$A = 0.115\,C + 0.346\left(H - \frac{O}{8}\right) + 0.043\,S,$$

where C, H, O and S are the percentages (by weight) of carbon, hydrogen, oxygen and sulphur in the fuel. This gives about 12 lb. of air per pound of combustible. In the best boiler practice, the weight of air required is from 16 to 20 lb. per pound of coal, but in actual practice, the air supplied varies between much wider limits. See article on *Boilers*.

COAL. — **The proximate analysis** of coal is made by separating a sample by successive heatings at different temperatures, into moisture, volatile matter, fixed carbon and ash. For the determination of moisture, a rather large sample, say 2 ounces or 60 grams, should be taken, crushed to about ¼-inch size, and heated for two hours to 140° C. (284° F.) or until the coal ceases to decrease in weight. If a finely crushed small sample is taken, much of the moisture may be lost by air-drying while crushing and weighing. For the

determination of the other constituents, a sample of about 1 gram of finely crushed coal is taken, dried for an hour at 105° C. (221° F.) and weighed, then heated at a red heat in a covered crucible until all the volatile matter is driven off, weighed, heated with a blast lamp to a white heat, the cover being off the crucible, until all the carbon is burned away, leaving the ash, which is weighed. The analysis should be reported as in the example below, the percentages being percentages of weight.

	Moist coal	Dry coal	Combustible
Moisture	10.0	.....	.....
Volatile matter	30.0	33.33	57.14
Fixed carbon	40.0	44.45	42.86
Ash	20.0	22.22	.....
	100.0	100.0	100.0

Classification of Coal. — The percentages of fixed carbon and volatile matter in the combustible furnish a means of classifying different kinds of coal. The writer's classification is as follows:

	Fixed carbon	Volatile matter	Heating value per lb. of combustible, B.t.u.
Anthracite	97 to 90	3 to 10	14,600 to 15,000
Semi-anthracite	90 to 85	10 to 15	14,700 to 15,500
Semi-bituminous	85 to 75	15 to 25	15,500 to 16,000
Bituminous, Eastern	75 to 60	25 to 40	14,800 to 15,500
Bituminous, Western	65 to 50	35 to 50	13,500 to 14,800
Lignite	Under 50	Over 50	11,000 to 13,500

Anthracite is hard, shiny, burns with little or no smoke, is slow to ignite, burns slowly and breaks into small pieces when rapidly heated. Anthracite is crushed at the mine and the lumps separated into different sizes by passing them over screens or parallel bars. The sizes are given the following names:

Lump, over bars set $3\frac{1}{2}$ to 5 inches apart;
Steamboat, over $3\frac{1}{2}$-inch mesh and out of screen;
Broken, over $2\frac{3}{4}$-inch mesh, through $3\frac{1}{2}$-inch mesh;
Egg, over 2-inch mesh, through $2\frac{3}{4}$-inch mesh;
Stove, over $1\frac{3}{8}$-inch mesh, through 2-inch mesh;
Chestnut, over $\frac{3}{4}$-inch mesh, through $1\frac{3}{8}$-inch mesh;
Pea, over $\frac{1}{2}$-inch mesh, through $\frac{3}{4}$-inch mesh;
Buckwheat, over $\frac{3}{8}$-inch mesh, through $\frac{1}{2}$-inch mesh;
Rice, over $\frac{3}{16}$-inch mesh, through $\frac{3}{8}$-inch mesh;
Culm, slack or screenings, through $\frac{3}{16}$-inch mesh.

Sizes larger than "pea coal" are prohibitive in price for power-plant use.

Semi-anthracite is similar to anthracite, but is less hard, less shiny and burns more rapidly. It can usually be distinguished by its tendency to soil the hands, while true anthracite does not.

Semi-bituminous coal is softer than semi-anthracite and has a greater tendency to smoke. It is one of the best steam coals.

Bituminous coal is also a soft coal. It is distinguished by high percentage of volatile matter, which causes it to give off dense volumes of smoke when heated. It requires careful firing and furnaces especially adapted for it to prevent smoke. There is a wide variation in its physical properties.

Lignite, or brown coal, is intermediate between coal and peat. It is brown in color, fragile and rapidly splits into fine pieces upon exposure to air.

The U. S. Geological Survey classifies coals into six groups, as follows: (1) anthracite; (2) semi-anthracite; (3) semi-bituminous; (4) bituminous; (5) sub-bituminous, or black lignite; and (6) lignite.

Classes 5 and 6 are described as follows:

Sub-bituminous coal is commonly known as "lignite," "lignitic coal," "black lignite," "brown coal," etc. It is generally black and shining, closely resembling bituminous coal, but it "weathers" or disintegrates more rapidly on exposure and lacks the prismatic structure of bituminous coal. Its calorific value is generally less than that of bituminous coal.

Lignite is commonly known as "lignite," "brown lignite" or "brown coal." It usually has a woody structure and is distinctly brown in color, even on a fresh fracture. It carries a higher percentage of moisture than any other class of coals, its mine samples showing from 30 to 40 per cent of moisture.

The following analyses of representative coals of the six classes are given by Prof. N. W. Lord:

Class 1. Anthracite Culm. Penn.
Class 2. Semi-anthracite. Arkansas.
Class 3. Semi-bituminous. W. Va.
Class 4(*a*). Bituminous coking. Connellsville, Pa.
Class 4(*b*). Bituminous non-coking. Hocking Valley, Ohio.
Class 5. Sub-bituminous. Wyoming, black lignite.
Class 6. Lignite. Texas.

COMPOSITION OF ILLUSTRATIVE COALS—CARLOAD SAMPLES

Proximate Analysis of "Air-dried" Sample

Heating Value of Coal. — The heating value of coal depends on its percentage of total combustible and on the heating value per pound of that combustible. The latter differs in different districts and bears a relation to the percentage of volatile matter as shown by the above table.

For coals in which the volatile matter is less than 40 per cent of the combustible, the heating value per pound of combustible may be approximately determined (within about 2 per cent) by means of the following table. When the volatile matter is in excess of 40 per cent, the figures in the table may have a plus or minus error of as much as 4 per cent, since the coals high in volatile matter differ greatly in their content of oxygen.

Volatile matter, per cent of combustible	Heating value, B.t.u. per pound of combustible	Volatile matter, per cent of combustible	Heating value, B.t.u. per pound of combustible	Volatile matter, per cent of combustible	Heating value, B.t.u. per pound of combustible
3	14,940	28	15,660	43	14,220
6	15,210	32	15,480	45	13,860
10	15,480	37	15,120	47	13,320
13	15,660	40	14,760	49	12,420
20	15,840				

The heating value of all the semi-bituminous coals, containing from 15 to 25 per cent of volatile matter in the combustible, is within $1\frac{1}{2}$ per cent of 15,750 B.t.u. per pound. This is within the limits of error of sampling, of chemical analysis or of calorimetric determination.

The heading value of any coal may also be calculated from the ultimate analysis by means of Dulong's formula,

$$\text{B.t.u. per pound} = 146\,C + 620\left(H - \frac{O}{8}\right) + 40\,S,$$

in which C, H, O and S are respectively the percentages by weight of carbon hydrogen, oxygen and sulphur. The probable error of this formula is not over 2 per cent for any coal containing less than 40 per cent volatile matter in the combustible. For coals higher in volatile matter, the error is sometimes larger. When the percentages are expressed as percentages of the various elements in the *combustible*, the formula gives the B.t.u. per pound of combustible; when the percentages are percentages of the various elements in a given weight of **coal**, the formula gives the B.t.u. per pound of coal, which is, of course, less than the B.t.u. per pound of combustible in proportion to the per cent of moisture and ash present. In general, if K be the per cent of combustible in a given sample, and H the heating value per pound of combustible, the heating value per pound of coal is $\frac{KH}{100}$.

For the direct determination of the heating value of coal or other solid fuel, a bomb calorimeter, in which the fuel is burned in an atmosphere of compressed oxygen, is the most accurate instrument. (*See Calorimeters, Fuel.*)

The Commercial Value of a Coal is not always in direct proportion to its heating value. Excessive moisture causes a reduction in its temperature of combustion, which reduction, in steam boiler practice, decreases the efficiency; excessive ash tends to obstruct the draft and thus cause imperfect combustion. High percentages of volatile matter tend to cause smoke and soot, and require the use of special furnaces.

Specifications for Coal. — For the reasons just stated, contracts for the purchase of coal on specifications of quality should penalize excess of moisture, ash and volatile matter above certain stated percentages. The author's specifications are as follows:

Anthracite and Semi-anthracite. — The standard is a coal containing 5 per cent volatile matter, not over 2 per cent moisture and not over 10 per cent ash. A premium of 0.5 per cent on the price will be given for each per cent of volatile matter above 5 per cent up to and including 15 per cent, and a reduction of 2 per cent on the price will be made for each 1 per cent of moisture and ash above the standard.

Semi-bituminous and Eastern Bituminous. — The standard is a semi-bituminous coal containing not over 20 per cent volatile matter, 2 per cent moisture and 6 per cent ash. A reduction of 1 per cent in the price will be made for each 1 per cent of volatile matter in excess of 25 per cent, and of 2 per cent for each 1 per cent of ash and moisture in excess of the standard.

Western Coals. — For western coals in which the volatile matter differs greatly in its percentage of oxygen, the above specification based on proximate analysis may not be sufficiently accurate, and it is well to introduce the heating value, as determined either by a calorimeter or by calculation from the ultimate analysis below:

The standard is a coal containing not over 6 per cent moisture and 10 per cent ash in an air-dried sample, and having a heating value of 14,500 B.t.u. per pound of pure coal (coal free from moisture and ash). For lower heating value per pound of pure coal, the price shall be reduced proportionally, and for every 1 per cent increase in ash or moisture above the specified figures, 2 per cent on the price shall be deducted.

Space Required for Storage.—The space occupied by a ton of coal depends both upon the quality of the coal and the size of the lumps. A ton of 2240 pounds of anthracite of pea size, or smaller, occupies a space of from 36 to 45 cubic feet. A ton or 2240 pounds of bituminous coal occupies a space of from 40 to 50 cubic feet. In estimating the space required for storage, 45 cubic feet per ton (2240 pounds) is usually assumed.

Weathering of Coal.—Anthracite coal when exposed to the weather undergoes practically no change except the oxidation of the sulphur content, which is small. Bituminous coal contains a larger percentage of sulphur, the oxidation of which, if present in sufficient amount, may develop sufficient heat to cause spontaneous combustion. Some lignites are rapidly disintegrated when exposed to the air. Experiments on carload lots of Illinois coal (*F. W. Wheeler, Trans. A.S.M.E.*, 1908) showed that the screenings and 3-inch nut coal lost 1.3 per cent of its heating value in one month, and 2 per cent in six months. Pillar coal in the mine, exposed underground twenty-two to twenty-seven years, showed only 3 per cent less heating value than the fresh face coal from the same mine.

Cost of Coal.—The cost of coal delivered to any power plant depends not only upon the quality of the coal and the size of the lumps, but also upon the cost of transportation, the railroad or water facilities for delivering the coal, and upon various conditions affecting the cost of mining. In making an estimate involving the cost of coal, one should obtain quotations from the dealers for the specific locality and time under consideration.

LIQUID FUEL.—(*See also Boilers; Gas Engines.*) Crude petroleum and various distillates of petroleum, such as gasoline, kerosene, etc., are largely used as fuel, the extent of their use in any locality depending chiefly on their relative cost as compared with coal. In Texas, California, Russia and other places near to oil wells and where coal is relatively expensive, petroleum has largely replaced coal as a fuel for steam boilers. Gasoline, kerosene and heavier oils are also extensively used in various types of internal combustion engines. Crude petroleum is composed chiefly of hydrocarbons, which distil at different temperatures, the lightest vapors being driven off as low as 113° F., and heavier vapors and oils at temperatures rising to 600°, above which waxes and residuum are formed. The crude oil contains small percentage of water, sulphur and oxygen as impurities. The specific gravity, weight and heating value of California oil are given as follows by J. N. LeConte (*Jour. A.S.M.E.*, *Aug.*, 1911):

CALIFORNIA OIL

Degree Baumé	Specific gravity	Weight per barrel, pounds	B.t.u. per pound	B.t.u. per barrel (42 gallons)
10	1.000	350	18,280	6,398,600
12	0.986	345	18,400	6,349,800
14	0.972	340	18,520	6,302,400
16	0.959	336	18,640	6,256,500
18	0.946	331	18,760	6,211,400
20	0.933	327	18,880	6,167,900
22	0.921	322	19,000	6,126,000
24	0.909	318	19,120	6,084,000
25	0.903	316	19,180	6,063,800

Oils from other sources have different densities and heating values, thus Lima, O., crude is reported to have a sp. gr. of 0.792; Beaumont (Texas) oil, sp. gr. 0.92, B.t.u. per pound 19,060; Pennsylvania heavy crude, sp. gr. 0.886, B.t.u. 20,736; Caucasian light crude, sp. gr. 0.884, B.t.u. 22,027. California oil, six lots, used in a boiler test at Redondo, Cal., contained moisture 1.82 to 2.70 per cent; sulphur 2.17 to 2.607; B.t.u. per pound 17,717 to 17,966.

The following table shows the relative heating values of crude petroleum and coal, based on oil of sp. gr. 0.885; B.t.u. per pound 20,000; 1 barrel, 42 gallons = 310 pounds.

Coal B.t.u. per pound	1 pound oil = pounds coal	1 barrel oil = pounds coal	1 ton (2240 pounds) coal = barrels oil
10,000	2	620	3.61
11,000	1.818	564	3.97
12,000	1.667	517	4.33
13,000	1.538	477	4.69
14,000	1.429	443	5.05
15,000	1.333	413	5.42

Cost. — The price of oil fluctuates much more than the price of coal. Prices should be obtained from local dealers at the time under consideration.

GASEOUS FUEL. — The use of gas as a fuel in power plants is confined almost entirely to its use in gas engines. (*See articles on Gas and Gas Engines.*)

FURNACES, ELECTRIC, AND ELECTRIC FURNACE PRODUCTS. — (*See also Electrochemical Processes, Industrial.*) Electric furnaces may be classified as follows:

Arc furnaces.
Induction furnaces.
Resistance furnaces.
- *a.* Current conducted by the materials heated:
  1. With electrolysis.
  2. Without electrolysis.
- *b.* Current conducted by a special resistor.

In the arc furnace the heat is produced by an electric arc (*see Arc, Electric*) usually between carbon electrodes. The induction furnace is essentially a static transformer (*see Transformers*) with the low-tension "winding" formed by the material to be heated. In the resistance furnace the current is supplied to the material to be heated (i.e., to the furnace "charge"), or to the special resistor, by connecting the charge or resistor directly to the source of the current supply. The heat developed in both the induction and resistance furnaces arises from the passage of the current through the resistance offered by the charge or special resistor.

The arc furnace may be considered a resistance furnace in which the resistor is a gas. Since the resistance of a gas at atmospheric pressure is greater than that of any solid resistor of the same dimensions as the arc, the amount of heat that can be produced in a small space will be greatest with an arc furnace.

TEMPERATURE AND DISTRIBUTION OF HEAT. — The advantage in electric heating is that a higher temperature can be produced than by using fuel, that the heat is produced inside the furnace where it is needed, and that the heat can be easily and accurately regulated. In the arc the hottest part of the positive carbon is estimated to be between 3900° C. and 4000° C. absolute. (*Waidner and Burgess, Bull. Bureau Stds., Vol. 1, p. 123, 1905.*) The temperature of the arc itself increases with the current. (*Kayser, Handbuch der Spektroscopie, Vol. 1, pp. 154–160, 1900.*)

The electric energy delivered to the furnace as heat is used as follows: (1) to heat the charge to the desired temperature, which involves heating up the furnace walls, if cold at the start. This energy is equal to the mass of the charge times the temperature rise times the specific heat. If the charge is melted or vaporized in the furnace, additional heat must also be supplied. This item may be reduced by delivering the charge to the furnace already hot as in steel refining. (2) To supply the energy needed for the reaction; the energy so required cannot be reduced. (3) To supply the loss due to conduction and radiation through the walls and electrodes, and the heat carried off by hot gases. A part of the heat carried off by hot gases may be recovered in heating water in boilers, so that it is not a complete loss.

MAXIMUM SIZE OF ELECTRIC FURNACES. — The largest workable capacity of an open-arc single hearth with a compact bundle of electrodes has been found in practice to be from 2500 to 3000 kilowatts at from 30,000 to 40,000 amperes and from 75 to 90 volts. These large sizes are always used with the three-phase system, so that the maximum total power absorption of a furnace is from 7500 to 9000 kilowatts. In carbide furnaces double three-phase furnaces are used with six electrodes, in place of three, in the same shaft, and the power absorbed is from 15,000 to 18,000 kilowatts. Great progress has been made in electric-furnace construction, by closing the furnace at the top and by having special means of feeding in the charge, thereby avoiding the dust nuisance and protecting the workmen from the heat, as well as distributing the

charge more uniformly. (*Taussig, VII Int. Cong. App. Chem., Sec. 10, p. 24, 1910; Trans. Faraday Soc., Vol. 5, p. 254, 1909; VIII Int. Cong. App. Chem., Vol. 21, p. 105, 1912.*)

DESIGN OF FURNACE WALLS. — To reduce the conduction of heat through the walls and electrodes to a minimum amount, these must be properly designed. The heat flow through the walls of three different shapes may be computed by the formulas below. In all cases

k = thermal conductivity of the walls, at the mean temperature $(t_1 + t_2)/2$. This coefficient k may be expressed in any convenient unit, e.g., gram calories per centimeter cube per second per ° C., or watts per inch cube per ° C. See article on *Heat and Thermal Properties* for values.

H = total heat conducted per second through the walls.

t_2 = temperature of the inside surface of the wall.

t_1 = temperature of the outside surface of the wall.

Hollow Rectangular Parallelopiped. —

$$H = \left(\frac{A}{\vartheta} + 0.54\,\Sigma l + 0.15\,n\vartheta\right)k(t_2 - t_1),$$

where A = the area of the six inner surfaces, ϑ = thickness of wall, Σl = the total length of all the inner edges, n = the number of corners. This applies where all three inner dimensions are greater than $\frac{1}{5}\vartheta$. (Langmuir, Adams, and Meikle, *Trans. Am. Electrochem. Soc., Vol. 14, p. 53, 1914.*)

Hollow Sphere. —

$$H = \frac{\pi k D d\,(t_2 - t_1)}{l},$$

where D = outside diameter of sphere, d = inside diameter, l = thickness of wall, all in the same unit.

Hollow Cylinder. —

$$H = \frac{2\pi k L\,(t_2 - t_1)}{2.3\log_{10}\dfrac{D}{d}} + \frac{\pi k D d\,(t_2 - t_1)}{2l},$$

where L = mean height of inner and outer walls, D = outside diameter, d = inside diameter, and l = thickness of top and bottom walls, all in the same unit. The first term gives the flow of heat through the cylindrical walls, the second the flow of heat through the top and bottom. (Hering, *Trans. Am. Electroch. Soc., Vol. 14, p. 215, 1908.*)

Linings and Composite Walls. — The most refractory substances do not have the lowest thermal conductivities. Consequently, it is advantageous to use a highly refractory substance only for the inner part or lining of the walls, using only such a thickness that the drop in temperature will be sufficient to permit of a less refractory substance of a lower conductivity being used for the next layer. "Graded" walls of several layers may be employed.

Refractories for Furnace Walls. — The most refractory substance is carbon, which however is a good heat conductor. Some of the products of the electric furnace, as silicon carbide and siloxicon (a substance containing varying amounts of carbon, silicon and oxygen) stand next to carbon as refractories, and do not have such high heat conductivities. (*See Fitzgerald, Electrochem. Ind., Vol. 2, p. 439, 1904.*) The numerical values of heat conductivities of refractories at high temperatures are known for only a few substances and then only approximately. See article on *Heat and Thermal Properties;* also article by Hering in *Met. and Chem. Eng.*, Vol. 9, p. 625, 1911, and *the table below for graphite and carbon.* For electrical conductivity see article on *Resistance and Conductance.*

DESIGN OF ELECTRODES FOR ELECTRIC FURNACES. — The electrodes of an electric furnace should be so designed that the energy will be carried into the furnace with a minimum energy loss. The loss due to the electrical resistance is directly proportional to the electrode's length; this should therefore be made as short as convenient. The loss due to electrical resistance will be smaller the greater the cross-section of the electrode, but the heat loss from the furnace through the electrode will be directly proportional to the cross-section. It is therefore possible to find a cross-section of a given material which will give a minimum total loss for a given length. The cross-section that would give the minimum loss on certain assumptions, only approximately true, is found from the equation

$$S = 0.346\, LI \sqrt{\frac{r}{k(t_2 - t_1)}},$$

and the loss itself, in gram calories, is

$$h = 2.89\, I \sqrt{kr}\,(t_2 - t_1),$$

where S = cross-section of electrode, L = its length, I = the current in amperes carried by the electrode, t_2 and t_1 the temperatures, in °C., of the hot and cold ends of the electrode respectively, r = its mean electrical resistivity in ohms per unit cube and k = its mean heat conductivity for the mean temperature $(t_1 + t_2)/2$. If S and L are in centimeters, r and k must be per cm.^{3}; if S and L are in inches, r and k must be per in.^{3}.

The values of k and r for carbon and graphite are not known accurately at high temperatures. The following values have been computed from measurements of Hering (*Trans. Am. Electroch. Soc., Vol. 17, p. 166, 1910*).

Material	Temperature °C.		Thermal cond. g-cal. per cm.^{3} per °C. per sec.	Electrical resistivity, ohms per cm.^{3}
	Hot end	Cold end		
Carbon	300	40	0.0891	0.00422
	701	50	0.124	0.00381
	902	60	0.130	0.00377
Graphite	355	66	0.399	0.000837
	516	70	0.325	0.000827
	707	87	0.309	0.000802

SMALL LABORATORY FURNACES. — A great variety of electric furnaces have been devised. A few typical laboratory furnaces will be described in this section. Some industrial furnaces are described in the next section:

Moissan's Furnace (Fig. 1). — Moissan's work was carried out in a furnace consisting of two horizontal electrodes, mounted so that the distance between the two ends could be adjusted longitudinally by a screw thread. An arc was formed between these electrodes in a cavity formed by some refractory material, such as lime. The substance to be heated was placed in a crucible under the arc as shown in Fig. 1. When the substance was not to be exposed to the gases of the arc, a furnace was made with a carbon tube passing through it at right angles to the electrodes and immediately below the arc. The substance to be heated was placed inside this tube.

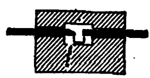

Fig. 1.

Borchers' Furnace (Fig. 2). — A type of furnace due to Borchers consists in a carbon rod placed between two larger electrodes. The charge is either packed around the small rod or placed under it. This type of furnace is convenient where a temperature below that of the arc is desired.

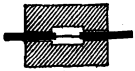

Fig. 2.

Héroult Furnace (Fig. 3). — A furnace that takes its name from Héroult consists in a crucible with one or more electrodes connected together above the crucible. The crucible is represented in Fig. 3 packed in carbon in an iron container. Graphite crucibles may be turned out from graphite electrodes. The charge in the crucible is usually melted by forming an arc between the crucible and the electrode above with an adjustable resistance in series with the arc. After the charge has melted the electrode may be partly immersed in the bath. In case it is desired to melt a substance in a crucible without the use of an arc, a smaller piece of carbon may be placed between the crucible and the electrode as in Borchers' furnace. If after the substance has been melted it is desired to pass the current through the bath itself, as, for example, in case a salt is to be electrolyzed, the upper electrode may be raised, the thin rod removed with a pair of tongs and the electrode then lowered into the bath. The salt will not solidify during this operation.

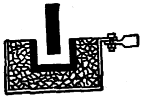

Fig. 3.

Arsem Furnace (Fig. 4). — It frequently happens in the laboratory that it is desired to heat a substance to a high temperature in a vacuum or in some pure gas, such as hydrogen or nitrogen. A very convenient furnace for this purpose has been designed by Arsem (*Trans. Am. Electroch. Soc., Vol. 9, p. 153, 1906*), and has been extensively employed in research work. This furnace may be obtained from the General Electric Company in more than one size. A vertical section is shown in Fig. 4. It consists of a chamber *A* and cover *B* made of a gun-metal casting turned true at the joint. A lead gasket *C*, 1/16 inch thick, forms an air-tight joint when the cover is fastened down by the cap-screws *D*. The tube *J* through which the air is removed from the furnace is soldered into the cover. The window *E* is a disk of clear white mica 0.005 inch thick clamped between lead washers *F*.

The electrodes *W* are brass tubing which are insulated from the cover. The clamps *UU* for holding the heater are copper. The heater *L* is a helix, usually of graphite, which is made by boring out a graphite electrode and cutting it along a spiral as shown. Metallic heaters may also be used. The lower end of the heater rests in the graphite cup which also holds the crucible support insulated from it by a lava ring. The screen for preventing radiation is a double-walled cylindrical box of Acheson graphite filled with graphite powder.

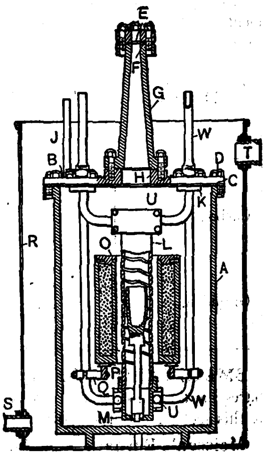

Fig. 4.

The water jacket *R* is a galvanized-iron tank provided with an inlet *S* and an outlet *T*. In a vacuum in the small size of furnace 9 to 10 kilowatts produce a temperature of 2500° C.

High-pressure Furnaces. — The Arsem furnace may be of course used with the internal pressure above an atmosphere, but it is not designed for high pressures. A furnace for working up to 200 atmospheres has been designed by Hutton and Petavel. (*Phil. Trans., Series A, Vol. 207, p. 421, 1908, and Electrochem. and Met. Ind., Vol. 6, p. 97.*) For a modified form see *Pring and Fairlie,* (*VIII Int. Cong. App. Chem., Vol. 21, p. 79, 1912*). For a furnace for spectroscopic work on gases at pressures up to 200 atmospheres, see *King, A. S., Astrophysical Journal, Vol. 28, p. 300, 1908.*

Heræus Furnace (Fig. 5). — A very useful type of furnace is due to the firm of Heræus. This consists in a tube wound in its middle portion with an electrical resistor. The ends of the tube are cooled by the air, or may be cooled by a coil of copper pipe through which water flows. The tube may be of some non-conducting substance, such as porcelain, in which case a ribbon of metal may be wound directly on the tube. Furnace tubes with grooves for winding with wire are now made by the Norton Company of Worcester, Mass., from fused alumina. These, however, are porous and cannot be used for a vacuum furnace. Glazed German porcelain may be heated up to 1180° C. and a vacuum maintained. At temperatures higher than this the glazing melts and air leaks into the tube. A nickel tube may be used for higher temperatures.

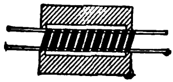

Fig. 5.

The metallic winding for carrying the current may be of platinum, nickel, nichrome, tungsten, molybdenum or any other suitable high-resistance material (*see Wires, Resistance*).

These furnaces are particularly useful when the temperature is to be held constant over a long period of time. For most purposes a constant current will keep the temperature sufficiently constant. For greater constancy some kind of regulator must be used (*see Bodenstein and Kranendieck, Z. f. Elektroch., Vol. 18, p. 417, 1912*). The Heræus type of furnace is usually more satisfactory when homemade, as a greater choice of materials is then possible.

Hoskins Furnace. — A convenient furnace for heating rather large crucibles or masses of material is made by the Hoskins Manufacturing Company of Detroit, Michigan. The heater consists of two rows of narrow, thin carbon plates which extend over two sides of the cavity which receives the substance to be heated. The contact resistance between the plates may be varied by pressure. This furnace of course requires a very large current at a low voltage.

Granular Carbon Furnace (Fig. 6). — A carbon or graphite crucible may be easily heated by placing it in a trough surrounded by granular gas carbon; this conducts better than coke. The current is passed through the trough, into which it is conducted by carbon rods. Clay crucibles should not be used in this way for temperatures over 1000° C., as at a high temperature they are attacked by the carbon.

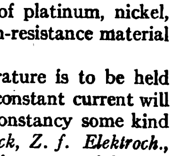

Fig. 6.

ELECTRIC-FURNACE PRODUCTS AND INDUSTRIAL FURNACES. — Some typical industrial furnaces and their products are described below.

Calcium Carbide. — Willson and Horry Furnaces. Calcium carbide was first made on a large scale by Willson in 1892 at Spray, N. C., by heating lime and carbon in an arc furnace. The reaction that takes place is

$$CaO + 3\,C = CaC_2 + CO.$$

The furnace consisted of a carbon plate 3 by 2.5 feet with a carbon electrode suspended above it. The whole was surrounded by brick walls. Furnaces similar to this were at first used at Niagara Falls, with the lower electrodes

mounted on a car which was removed when filled with an ingot of carbide. Later the Horry rotary furnace was used (*U. S. Pat. 656,156*). The Carbide Company keeps the style of their present furnace secret. In Europe the Willson type of furnace is used. Carbide may be either formed in an ingot in the crucible of the furnace and removed solid, or it may be drawn off in the liquid state. When an ingot is formed it has been found better to have the current flow between two electrodes suspended over the crucible, in place of having the crucible form one electrode. (*Conrad, Electrochem. and Met. Ind., Vol. 6, p. 397, 1908.*) The purity of the carbide is in the neighborhood of 80 per cent. The yield of 80 per cent carbide is about 5 kilograms per 24 kilowatt hours.

Carborundum. — Acheson Process. — Silicon carbide or carborundum was first made on a large scale by Acheson. It is produced from quartz and carbon when these substances are heated in an electric-resistance furnace, according to the reaction

$$SiO_2 + 3\,C = CSi + 2\,CO.$$

The furnace has a granular carbon core around which the charge, consisting of quartz, carbon, sawdust, and sodium chloride, is packed. The latest furnaces are 9.15 meters long by 3.67 meters wide, and absorb 1600 kilowatts. The current is 20,000 amperes (*Min. Industry, Vol. 16, p. 155, 1907; Vol. 17, p. 112, 1908*). From measurements on a 750-kilowatt furnace it was found that the carbide is formed at 1840° C. and decomposes when heated above 2240° C. (*Saunders, Trans. Am. Electroch. Soc., Vol. 21, p. 425, 1912.*) The yield is about one kilogram of crystallized carbide for 8.5 kilowatt hours. Silicon carbide is used as an abrasive, as furnace linings and as a substitute for ferro-silicon in the manufacture of steel. (*Fitzgerald, Carborundum, Vol. 13, in the Engelhardt Monographien über angewandte Elektrochemie.*)

Silundum is the trade name for silicon carbide made by exposing hot carbon rods to silicon vapor. These rods are used for electric heating.

Siloxicon is a product of the incomplete reduction of silica, and may be represented by the formula SiCO, though compounds with varying proportions of these elements are found. Siloxicon is used for crucible linings. It is made by heating silica and an insufficient quantity of carbon for complete reduction of the silica.

Silicon is made in an arc furnace from coke and sand. At the high temperature produced the silica is completely reduced and the melted metal is drawn off in amounts weighing from 600 to 800 pounds. It varies from 90 to 97 per cent in purity (*F. J. Tone, Electrochem. and Met. Ind., Vol. 7, p. 192, 1900; Min. Industry, Vol. 17, p. 768, 1908*).

Graphite. — Berthelot (*Ann. de Chem. et de Phys., Series 4, Vol. 19, p. 393, 1870*) defines graphite as that allotropic form of carbon which when oxidized at low temperature with powerful oxidizing agents (potassium chlorate and nitric acid) gives graphite oxide. Arsem suggests as a definition for graphite that it is that allotropic form of carbon whose density lies between 2.25 and 2.26. (*Trans. Am. Electroch. Soc., Vol. 20, p. 105, 1911.*)

Graphite is made by heating carbon, containing a small amount of impurity, to a high temperature in an electric resistance furnace. Anthracite coal is graphitized in bulk; electrodes and crucibles are also graphitized after moulding. Acheson's theory of the formation of graphite is that the carbon first forms a carbide, which decomposes at a higher temperature, leaving the carbon in the form of graphite. This theory is not confirmed by Arsem's experiments. (*See Fitzgerald, Künstlicher Graphit, Vol. 15 of the Engelhardt Monographien über angewandte Elecktrochemie.*)

Carbon Bisulphide is made in a specially designed furnace by heating together sulphur and carbon. Most of the disagreeable features encountered in the manu-

facture of this substance are thus avoided. (*Taylor, Trans. Am. Electroch. Soc., Vol. 1, p. 115, 1902; Vol. 2, p. 185, 1902.*)

Phosphorus is a substance the production of which the use of the electric furnace has much simplified. It is made in the Readman-Parker furnace according to Wöhler's process:

$$Ca_3(PO_4)_2 + 3\,SiO_2 + 5\,C = 3\,CaSiO_3 + 5\,CO + 2\,P.$$

(*Min. Industry, Vol. 6, p. 537, 1897; Vol. 7, p. 557, 1898.*)

Alundum is the trade name of fused aluminum oxide, which is made by the Norton Company of Worcester. Aluminum oxide is fused in an arc furnace. (*Min. Industry, Vol. 19, p. 28, 1910.*) Fused aluminum is used as an abrasive, as a refractory substance for furnace linings, and porous crucibles of this substance are used in analytical laboratories.

Aluminum. — Hall and Héroult Processes. — Aluminum is now produced by the electrolysis of a solution of alumina in fused cryolite ($AlF_3.3\,NaF$) to which other fluorides, such as those of aluminum and of sodium, are added in some factories. The aluminum sinks to the bottom of the crucible and is drawn off. This process was discovered nearly simultaneously by C. M. Hall and Héroult. The heat developed by the current in passing through the solution is sufficient to keep the bath melted. The cathode is an iron trough lined with carbon, and the anode consists of a number of carbon rods suspended over the crucible. The Aluminum Company of America uses as anode for one crucible 48 carbon rods 3 inches in diameter and 15 inches long. The electromotive force applied to each crucible is 5.5 volts; the current is 10,000 amperes. The yield is 1.75 pounds of aluminum per horse-power day. For further information see *Min. Industry, Vols. 6, 14, 15, 17, 20.*

Sodium, Potassium. — Castner Process. — Sodium and potassium are obtained by the electrolysis of their fused hydrates, usually in the cell designed by Castner (*U. S. Pat. 453,030, filed 1890; see also Becker, Die Elektromettallurgie der Alkalimettale*). At Holcomb's Rock, Va., sodium is made by the electrolysis of fused sodium chloride. (*Mineral Ind., Vol. 19, p. 614, 1910.*)

Calcium is made by the electrolysis of fused calcium chloride, to which calcium fluoride is added to lower its melting point. Calcium is made at Holcomb's Rock, Va., probably in a cell devised by Seward and Von Kügelgen (*U. S. Pat. 880,760, 1908; Min. Industry, Vol. 16, p. 131, 1907; Vol. 17, p. 99, 1908*); and abroad by the method of Rathenau (*Z. f. Elektroch., Vol. 10, p. 508, 1907*). In the Ratheneau method the cathode is an iron rod which just touches the surface of the melted calcium chloride. The calcium solidifies when deposited on the cathode by electrolysis. As the calcium grows the rod is withdrawn so that a rod of calcium is produced.

Zinc may be made by the electrolysis of fused zinc chloride. In the Swinburne-Ashcroft process sodium chloride is added to zinc chloride in such quantity that the resulting mixture contains 28 per cent zinc. The cell is a brick-lined, sheet-iron vessel. The anode is carbon, the cathode, melted zinc. Each vat takes 4.5 volts, with a cathode current density of 400 amperes per sq. ft. The temperature of the fused salt is 450° C. (*Electroch. and Met. Ind., Vol. 3, p. 65, 1905.*)

Magnesium is made by the electrolysis of fused carnallite ($MgCl_2.KCl.6\,H_2O$) and floats to the surface of the salt, which is, of course, anhydrous when melted.

ELECTRIC FURNACES IN METALLURGY. — Under special local conditions, where iron ore is plentiful, where coke is expensive and where power is cheap, the electric reduction of iron ore is carried out commercially, as at Trollhätten and Domnarfvet, Sweden, and at Héroult, California. The furnaces

have a shaft resembling a blast furnace, with a crucible at the base into which the electrodes project in a slanting position. (*For detailed accounts, see volumes of the Met. and Chem. Eng.*) More recently it has been found better to have the electrodes vertical. (*Taussig, VIII Int. Congress App. Chem., Vol. 21, p. 105, 1912.*)

Electric tin smelting has been tried on a commercial scale with apparent success (*Met. and Chem. Eng., Vol. 9, p. 453, 1911*) as well as the smelting of copper and nickel (*Met. and Chem. Eng., Vol. 11, p. 22, 1913*), and zinc (*see volumes of the Met. and Chem. Eng.*). The use of electric furnaces in steel refining and in the production of ferro-alloys is much more extensive for in this case power does not need to be so cheap as in the reduction of iron ore.

Steel Refining. — Usually the steel which is refined in electric furnaces is taken from Bessemer converters or open-hearth furnaces and poured directly into the electric furnace. The advantages of the electric furnaces are (*Walker, Met. and Chem. Eng., Vol. 10, p. 371, 1912*):

1. Complete removal of oxygen,
2. Absence of oxides caused by additions, such as silicon manganese,
3. Production of electric steel ingots of 8 tons and less that are practically free from segregation,
4. Reduction of sulphur to 0.005 per cent if desired,
5. Reduction of phosphorus to 0.005 per cent as in the basic open-hearth process, but with complete removal of oxygen.

There are in operation over 70 electric steel furnaces of different types in Europe and America (*Walker*).

The recent progress in electric steel refining consists in an improvement in existing methods and in a reduction of costs. While in 1911 it was considered good practice to melt and refine steel scrap in six hours at 750 kilowatt hours per ton, the same operation is now carried out in four hours with 600 kilowatt hours. (*Héroult, VIII Int. Cong. of App. Chem., Vol. 21, p. 59, 1912.*)

Some of the types of furnaces used in steel refining are the following:

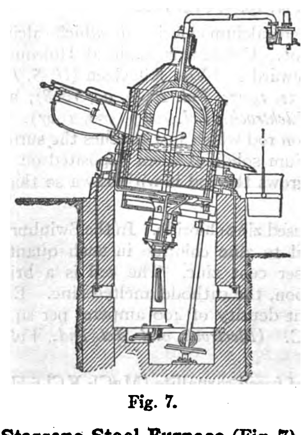

Fig. 7.

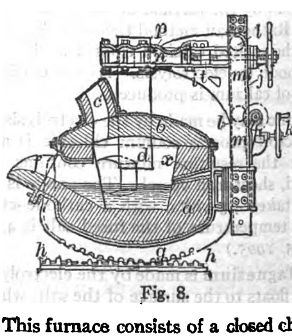

Fig. 8.

Stassano Steel Furnace (Fig. 7). — This furnace consists of a closed chamber with three electrodes connected to a three-phase system above the slag. The furnace rotates so as to stir all of the metal. This furnace is used in Italy, Odessa, and Newcastle-on-Tyne (*Met. and Chem. Eng., Vol. 10, p. 66, 1912.*)

Héroult Steel Furnace (Fig. 8). — This furnace consists of a crucible lined with refractory material. Carbon electrodes project into it through the roof. An arc is formed where the current passes from each electrode into the slag. The power is regulated by an electrical automatic regulator which moves the electrodes up and down as required.

Girod Steel Furnace. — This furnace consists of a crucible with several soft-steel rods projecting through the base. These form one electrode; the other is one or more carbon rods suspended from above. The steel electrodes of course melt several inches below the surface of the refractory lining of the crucible. The furnaces are sold by C. W. Leavitt and Co., 30 Church St., New York, from whom the following data have been obtained.

These furnaces require from 65 to 70 volts at frequencies from 25 to 50 cycles. The power factor is about 80 per cent and the duration of heat when the metal is charged in the melted state is 1½ to 2½ hours. The number of electrodes are from 1 to 3, according to the capacity of the furnace. For a furnace of about 12 tons capacity, the maximum power required is 1200 kilowatts measured at the terminals of the electric generator; the energy consumption when the metal is charged cold is 900 kilowatt hours per ton of steel; with a melted charge, from 150 to 250 kilowatt hours. The electrodes are so designed that the current does not exceed 5 amperes per square inch of cross-section. The number of consecutive heats possible without repairs is:

	Linings	Cover	Electrodes
With cold charge....................	30 to 40	20 to 30	10
With melted charge..................	60 to 90	40 to 50	20

To handle the furnace 6 persons are necessary: a melter, 2 assistant melters, 2 workmen and a boy.

Other Resistance Furnaces more or less similar to the Héroult furnace are the Keller furnace (*Trans. Am. Electroch. Soc., Vol. 15, p. 96, 1909*) and the Nathusius furnace (*Met. and Chem. Eng., Vol. 10, p. 227, 1912*).

Induction Furnaces. — Induction furnaces are transformers in which a melted ring of steel is the secondary. The Kjellin furnace, Fig. 9, consists of a single deep ring of metal. It has only a small area of contact between the metal and slag, and the slag is not easily heated. The use of this furnace is therefore restricted in its application (*Kjellin, Trans. Am. Electroch. Soc., Vol. 15, p. 175, 1909*).

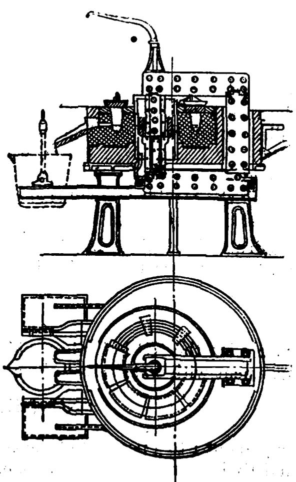

Fig. 9.

A modified form of induction furnace is the Röchling-Rodenhauser furnace. This furnace has two annular rings combined in the form of a figure 8. The central portion carries the currents induced in both circuits, as well as a current from electrodes supplied by extra secondary coils. This current passes through the lining of the furnace, which has sufficient conductivity when hot.

These furnaces, as well as another modification, known as the Frick furnace, can be obtained from Siemens and Halske, represented in this country by Dr. G. K. Frank, 80 West St., New York. Another design of induction furnace is due to Hiorth (*Trans. Am. Electroch. Soc., Vol. 20, p. 293, 1911*).

Pinch Effect in Induction Furnaces. — The magnitude of the current which can be sent through a trough of melted metal is limited by the so-called pinch effect (*Trans. Am. Electroch. Soc., Vol. 11, p. 329, 1907*). On account of the attraction of the current elements for each other, a compressing force is exerted on the metal which causes a decrease in the cross-section at some point. If the current is too great the metal may be entirely separated and the circuit broken.

Ferro-Alloys. — Ferro-alloys were originally made from iron ore, the oxide of other metal, carbon, and flux, but on account of impurities, scrap iron and steel shavings are now used in place of iron ore (*Met. and Chem. Eng., Vol. 8, p. 133, 1910*). Arc and resistance furnaces similar to those used for steel refining are used.

Ferro-Silicon is the most important of the ferro-alloys. It is made from iron, quartzite, and carbon. At the Keller-Leleux works at Livet it has been found practicable to turn out 20 tons of 30 per cent ferro-silicon with 4000 horse-power during a day. (*See preceding reference.*) For an account of the uses of the other ferro-alloys, see *Electrochem. Ind., Vol. 1, p. 583, 1903; Electrochem. and Met. Ind., Vol. 4, p. 247, 1906.*

FIXATION OF ATMOSPHERIC NITROGEN. — One of the most important applications of the electric furnace is the fixation of atmospheric nitrogen. The various processes employed are described below.

Carbide Method. — In this method calcium carbide is heated in pure nitrogen, forming calcium cyanide according to the reversible reaction

$$CaC_2 + N_2 \rightleftarrows CaCN_2 + C.$$

The carbide is heated in iron drums by a thin carbon conductor running through the center of the drum. Heat is evolved by the reaction. The product is called "nitro-lime" or "lime-nitrogen," and contains 12 to 15 per cent nitrogen. (*Met. and Chem. Eng., Vol. 5, p. 78, 1907.*) It is used directly as a fertilizer, or may be converted into ammonia by superheated steam. The yield in nitrogen by the carbide method is about 51.6 grams per kilowatt hour, including the manufacture of the carbide.

Direct-Oxidation Method. — In this method the nitrogen and oxygen in air are caused to combine in a high-voltage arc according to the reversible reaction

$$N_2 + O_2 \rightleftarrows 2\ NO.$$

On cooling the NO is further oxidized to nitric dioxide. The nitric dioxide on treatment with water gives nitric and nitrous acids:

$$2\ NO_2 + H_2O = HNO_3 + HNO_2.$$

Only about 1 to 3 per cent of the air treated is oxidized. The yield in the Birkeland-Eyde furnace is 12.7 grams of nitrogen fixed per kilowatt hour. (*Trans. Faraday Soc., Vol. 2, p. 98, 1906.*) Furnaces of three different designs are now in operation for oxidizing nitrogen: that of Birkeland and Eyde, that of Schönherr, and that of H. and G. Pauling.

Direct Synthesis of Ammonia. — In this method, due to Haber, ammonia is formed directly from a mixture of nitrogen and hydrogen by passing over a

catalyzer between 500° C. and 700° C. at 200 atmospheres, according to the reversible reaction

$$\tfrac{1}{2} N_2 + \tfrac{3}{2} H_2 \rightleftarrows NH_3.$$

(*Zeit. f. Elektroch., Vol. 16, p. 244, 1910; Vol. 19, p. 53, 1913.*) The efficiency of this process has not been made public.

Serpek Process. — In this process aluminum nitride is made by heating aluminum oxide, carbon, and nitrogen together. On heating the aluminum nitride with water, ammonia and aluminum hydrate are formed. The product obtained from the furnace is said to contain 20 to 24 per cent of nitrogen, and the power required per unit of nitrogen is said to be only one-half of that used in the calcium-carbide method. (*Bull. de la Soc. ind. de Mulhouse, Vol. 79, p. 39, 1909. U.S. Pat. 996,032, 1911.*)

[M. DeK. Thompson.]

FUSES. — (*See also Circuit Breakers; Wiring of Buildings.*) Metal strips or wires which open electric circuits by melting or fusing when the current reaches a predetermined value are called fuses. They were used in the earliest electric plants to furnish automatic protection for feeder and generator circuits. Their use is now confined largely to low-voltage distribution circuits and to the protection of small pieces of apparatus such as motors and small-capacity transformers.

All fuses have an inherent time-element feature due to the fact that the current must heat the fuse metal up to its melting temperature. This time lag varies with the size and type of fuse, the large ones in general taking longer to reach their fusing temperature than the smaller sizes, due to their thermal capacities. There are three designs of fuses in general use, namely, the open or link, the expulsion, and the enclosed or cartridge types. The choice of type depends upon the service for which the fuse is intended.

RATING OF A FUSE.—The rating of a fuse depends somewhat on its type and general design. Fuses will, as a rule, carry their normal rated current indefinitely but will blow at a certain overload varying from 15 per cent in an enclosed fuse to about 80 per cent in an open fuse if the overload continues a sufficient length of time. For greater overloads the length of time required for blowing diminishes rapidly.

OPEN OR LINK FUSES were the original type of automatic protection. The early ones were small copper wires and had the drawback of forming copper globules and of possessing a high fusion temperature. In order to reduce the temperature of the molten metal there were employed alloys of low fusing points made of lead, tin, or other metals. These fuses were soft and were easily damaged when tightening up the contact nuts. The next step was to use alloy fuses with copper tips, and these are still used to some extent.

As the price of aluminum was reduced this material was used largely for fuses as it has a high conductivity (thus reducing the amount of metal to be fused), a fairly low melting point and almost complete vaporization of the metal fused. By using wide strips of aluminum cut to form two or more bridges, fairly reliable open fuses can be made up to 1200 amperes capacity.

Any metal strip which is exposed to drafts is apt to be very erratic in its behavior as a fuse. To protect link fuses from drafts, and also to remove the danger from molten metal which may be thrown at the time of blowing, it is desirable to install them in porcelain fuse boxes.

EXPULSION FUSES consist essentially of open fuse wires or strips placed in a holder, so designed that the expulsion of the gases formed by the melting of the fuse blows out the arc. The earliest designs of this type comprised a removable fuse holder of lignum vitæ or similar tough, close-grained wood, equipped with terminals which fitted into suitable blocks. Later types have the fuse placed in a fiber tube and arranged to blow out through one end like a bomb.

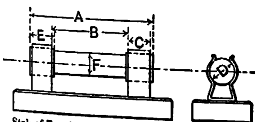
The fuses used for the protection of distributing transformers mounted on poles or houses are usually of the expulsion type. For such outdoor service a combination fuse and disconnecting switch is frequently used. Modifications of the expulsion-type fuse were formerly used to advantage in railway service, but in recent car equipments circuit breakers have practically replaced fuses and cut-outs.

INCLOSED OR CARTRIDGE FUSE.—This type of fuse consists essentially of a fusible wire, strip or sets of wires and strips inclosed within a tube or cartridge usually of fiber. The tube is filled with a material to exclude the

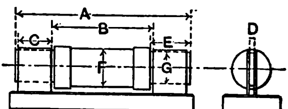
air and to facilitate the opening of the circuit when the fuse blows by absorbing the gases formed and chilling out the arc. Suitable terminals are provided so that the fuse may be mounted in a fuse block.

National Electrical Code Fuses. — When inclosed fuses were first put on the market each manufacturer developed his own spacings and designs of terminals, so that there was no uniformity and the fuse of one manufacturer could not be used in the fuse holder of another manufacturer. To avoid this confusion the representatives of the fuse builders and the National Board of Fire Underwriters finally adopted the standard dimensions and types of contacts given in the accompanying table. Up to 60 amperes ferrule type contacts (i.e., cylindrical metal ends) are used and from 61 to 600 amperes knife-blade contacts are employed. One set of dimensions are used for fuses up to 250 volts and another for fuses up to 600 volts. Fuses that correspond to the accepted dimensions and that meet other requirements agreed on are known as National Electrical Code (N. E. C.) fuses and are interchangeable. Fuses are made for higher voltages than 600 volts and larger currents then 600 amperes, but they have not been accepted by the National Board of Fire Underwriters.

DIMENSIONS OF N. E. C. CARTRIDGE FUSES



Style of Terminal for Cartridge Fuses
0-60 Amperes



Style of Terminal for Cartridge Fuses
61-600 Amperes

			A	B	C	D	E	F	G
Voltage	Rated capacity		Length over terminals	Distance between contact clips	Width of contact clips	Diameter of ferrules or thickness of terminal blades	Min. length of ferrules or of terminal blades outside of tube	Diameter of tube	Width of terminal blades
	Amp.		Inches	Inches	Inches	Inches	Inches	Inches	Inches
0–250	0–30	Form 1	2	1	½	9/16	½	½	. . .
	31–60	Form 1	3	1¾	⅝	13/16	⅝	¾	. . .
	61–100	Form 2	5⅞	4	⅞	⅛	1	1	¾
	101–200	Form 2	7⅛	4½	1¼	3/16	1⅜	1½	1⅛
	201–400	Form 2	8⅝	5	1¾	¼	1⅞	2	1⅝
	401–600	Form 2	10⅜	6	2⅛	¼	2¼	2½	2
251–600	0–30	Form 1	5	4	½	13/16	½	¾	. . .
	31–60	Form 1	5½	4¼	⅝	1 1/16	⅝	1	. . .
	61–100	Form 2	7⅞	6	⅞	⅛	1	1¼	¾
	101–200	Form 2	9⅝	7	1¼	3/16	1⅜	1¾	1⅛
	201–400	Form 2	11⅝	8	1¾	¼	1⅞	2½	1⅝

Cost of N. E. C. Fuses. — In moderate quantities of standard packages the price of 30-ampere 250-volt fuses is about 15 cents each, and of 400-ampere 600-volt fuses about $3.30 each. The others fall between these limits.

Plug Fuses. — A plug fuse is a fuse mounted in a plug of the standard Edison-lamp base dimensions. They are in common use on lighting and power circuits up to 30 amperes capacity. The outer face of the plug usually has a mica covering which is discolored by the blowing of the fuse. A brass cap is also sometimes used as a cover.

SPECIFICATIONS FOR FUSES. — The following memoranda are intended to assist in writing specifications. See also articles on *Specifications*.

Open or inclosed. Wire or ribbon. Current to blow fuse in a specified time. To blow without violence at a stated current. Voltage of circuit above ground.

[S. Q. Hayes.]

GAGES, SHEET-METAL. — (*See also Copper; Gages, Wire; Iron, Wrought; Steel.*) There are two principal gages for sheet iron and steel used in the United States, one established by Act of Congress in 1893 and the other recommended by a joint committee of the American Society of Mechanical Engineers and the American Railway Master Mechanics Association.

U. S. Standard Gage. — The former gage, which is known as the U. S. Standard Gage, is based upon the fact that a cubic foot of iron weighs 480 pounds. The scale of this gage has been arranged so that each gage number represents a certain number of ounces in weight, or an equal number of 640ths of an inch in thickness. This gage is used for determining duties and taxes levied on sheet and plate iron and steel, and in its application a variation of 2½ per cent either way is allowable.

Decimal Gage. — The latter gage, which is known as the Decimal Gage, is not based upon the weight but upon the thickness of the metal. Each number of the gage is the number of thousandths of an inch of thickness. This gage has been adopted recently by the Association of American Steel Manufacturers, the American Railway Master Mechanics' Association, and by most of the principal railroads of the United States, Canada and Mexico. The decimal system of gaging was recommended by the American Institute of Mining Engineers in 1877 and by the American Society of Mechanical Engineers in 1895.

Brown and Sharpe Gage. — Copper and brass plates are rated by the Brown and Sharpe gage. The plate thicknesses on this gage correspond to the diameters on the American Wire Gage. (*See Gages, Wire.*)

The following tables give the dimensions and weights of sheet metal according to gages described above.

U. S. STANDARD GAGE FOR SHEET AND PLATE, IRON AND STEEL

[WM. A. DEL MAR.]

GAGES, WIRE. — (*See also Gages, Sheet Metal.*) The sizes of wires having a diameter less than ½ inch are usually stated in terms of certain arbitrary scales called "gages." The size or gage number of a solid wire refers to the cross-section of the wire perpendicular to its length; the size or gage number of a stranded wire refers to the total cross-section of the constituent wires, irrespective of the pitch of the spiraling. Larger wires are usually described in terms of their area expressed in circular mils. A circular mil is the area of a circle 1 mil in diameter, and the area of any circle in circular mils is equal to the square of its diameter in mils. See *Units and Conversion Factors.*

There are a number of wire gages in use, the principal ones being the following.

AMERICAN OR BROWN AND SHARPE WIRE GAGE. — This gage is the one commonly used in the United States for copper, aluminum and resistance wires. The gage is designated by either of the abbreviations A. W. G. or B. & S.

Basis of the A. W. G. or B. & S. Gage. — The diameter of wires having successive numbers on this gage are in the ratio of $\sqrt[39]{92}$ (= 1.1229 approx.) to 1, and the No. 36 wire has a diameter of 5 mils. No. 35 A. W. G., therefore, has a diameter of $5 \times 1.1229 = 5.61$ mils and so on until No. 0000 is reached, having a diameter of 460 mils.

The ratio $\sqrt[39]{92}$ is approximately equal to $\sqrt[6]{2}$, which is 1.1225. This circumstance makes it possible to have a group of wires of regular gage size with an aggregate area approximately equal to that of another regular gage size.

The following approximate relations are also useful:

An increase of 1 in the number increases the resistance 25 per cent.
An increase of 2 in the number increases the resistance 60 per cent.
An increase of 3 in the number increases the resistance 100 per cent.
An increase of 10 in the number increases the resistance 10 times.

A No. 10 A. W. G. copper wire has the following approximate characteristics:

Ohms per 1000 feet	1
Circular mils area	10,000
Weight, pounds per 1000 feet	32

A No. 10 A. W. G. aluminum wire has the following approximate characteristics:

Ohms per 1000 feet	1.6
Circular mils area	10,000
Weight, pounds per 1000 feet	9.5

Remembering these rules it is easy to find the approximate size, resistance, area, or weight of any size wire. For example, a No. 12 A.W. G. copper wire has a resistance of 1 plus 60 per cent = 1.6 ohms per 1000 feet approximately. Its area, being inversely as its resistance, is $\frac{10,000}{1.6} = 6250$ circular mils; its diameter is therefore $\sqrt{6250} = 79$ mils and its weight, $\frac{32}{1.6} = 20$ pounds per 1000 feet.

U. S. STEEL WIRE GAGE. — This gage, known also as the "Washburn and Moen," "Roebling," "American Steel and Wire Co.'s" gage, is the one usually employed in the United States for steel and iron wire. It is frequently abbreviated "S. W. G.," but to avoid confusion with the British Standard Wire Gage (*see below*) it should be abbreviated "Stl. W. G." or "A. (steel) W.G."

BIRMINGHAM (OR STUBS') WIRE GAGE.—This gage is still used in the United States for some purposes, e.g., to designate the size of brass wire, and is also employed to a limited extent in Great Britain. It is usually abbreviated "B. W. G." It is sometimes referred to as the "Stubs'" gage, but it should not be confused with the Stubs' Steel Wire Gage.

BRITISH STANDARD WIRE GAGE.—This gage, usually called simply the "Standard Wire Gage," and abbreviated "S. W. G.," is also known as the "New British Standard" (abbreviated "N. B. S."), the English Legal Standard, or the Imperial Wire Gage, and is the legal standard of Great Britain for all wires, as fixed by order in Council, August 23, 1883. It was constructed by modifying the Birmingham Wire Gage, so that the differences between successive diameters were the same for short ranges, i.e., so that a graph representing the diameters consists of a series of a few straight lines.

EDISON WIRE GAGE.—The size of a wire on this gage is equal to its cross-sectional area in circular mils divided by 1000. For example, a solid wire 0.2 inch in diameter has the number $(200)^2/1000 = 40$. This gage is now rarely used.

OTHER GAGES.—In addition wire sizes are sometimes specified in terms of the "Old English Wire Gage," known also as the "London Gage," and the "Stubs' Steel Wire Gage."

COMPARISON OF WIRE GAGES.—A comparison of the different gages, in terms of the diameters (in mils or thousandths of an inch) of solid wires corresponding to the various numbers, is given below. The cross-section in circular mils is the square of the diameter in mils.

COMPARISON OF WIRE GAGES

GALVANIZING FOR IRON OR STEEL, Specification for Acceptance Test. — These specifications give in detail the test to be applied to galvanized material, as recommended by the Electric Railway Engineering Association, the National Electric Light Association, etc. All specimens shall be capable of withstanding these tests.

(a) **Coating.** — The galvanizing shall consist of a continuous coating of pure zinc of uniform thickness, and so applied that it adheres firmly to the surface of the iron or steel. The finished product shall be smooth.

(b) **Cleaning.** — The samples shall be cleaned before testing, first with carbona, benzine or turpentine, and cotton waste (not with a brush), and then thoroughly rinsed in clean water and wiped dry with clean cotton waste.

The sample shall be clean and dry before each immersion in the solution.

(c) **Solution.** — The standard solution of copper sulphate shall consist of commercial copper sulphate crystals dissolved in cold water, about in the proportion of 36 parts, by weight, of crystals to 100 parts, by weight, of water. The solution shall be neutralized by the addition of an excess of chemically pure cupric oxide (CuO). The presence of an excess of cupric oxide will be shown by the sediment of this reagent at the bottom of the containing vessel.

The neutralized solution shall be filtered before using by passing through filter paper. The filtered solution shall have a specific gravity of 1.186 at 65° F. (reading the scale at the level of the solution) at the beginning of each test. In case the filtered solution is high in specific gravity, clean water shall be added to reduce the specific gravity to 1.186 at 65° F. In case the filtered solution is low in specific gravity, filtered solution of a higher specific gravity shall be added to make the specific gravity 1.186 at 65° F.

As soon as the stronger solution is taken from the vessel containing the unfiltered neutralized stock solution, additional crystals and water must be added to the stock solution. An excess of cupric oxide shall always be kept in the unfiltered stock solution.

(d) **Quantity of Solution.** — Wire samples shall be tested in a glass jar of at least two (2) inches inside diameter. The jar without the wire samples shall be filled with standard solution to a depth of at least four (4) inches. Hardware samples shall be tested in a glass or earthenware jar containing at least one-half (½) pint of standard solution for each hardware sample. Solution shall not be used for more than one series of four immersions.

(e) **Samples.** — Not more than seven wires shall be simultaneously immersed, and not more than one sample of galvanized material other than wire shall be immersed in the specified quantity of solution.

The samples shall not be grouped or twisted together, but shall be well separated so as to permit the action of the solution to be uniform upon all immersed portions of the samples.

(f) **Test.** — Clean and dry samples shall be immersed in the required quantity of standard solution in accordance with the following cycle of immersions.

The temperature of the solution shall be maintained between 62° and 68° F. at all times during the following test.

First. Immerse for one minute, wash and wipe dry.
Second. Immerse for one minute, wash and wipe dry.
Third. Immerse for one minute, wash and wipe dry.
Fourth. Immerse for one minute, wash and wipe dry.

After each immersion the samples shall be immediately washed in clean water having a temperature between 62° and 68° F., and wiped dry with cotton waste.

In the case of No. 14 galvanized iron or steel wire, the time of the fourth immersion shall be reduced to one-half minute.

(g) **Rejection.** — If after the test described in section "f" there should be a bright metallic copper deposit upon the samples, the lot represented by the samples shall be rejected.

Copper deposits on zinc or within one inch of the cut end shall not be considered causes for rejection.

In the case of a failure of only one wire in a group of seven wires immersed together, or if there is a reasonable doubt as to the copper deposit, two check tests shall be made on these seven wires and the lot reported in accordance with the majority of the sets of tests.

[W. A. Del Mar.]

GALVANOMETERS. — (*See also Ammeters; Electrodynamometers; Fluxmeter; Voltmeters.*) The essential parts of a galvanometer are a permanent magnet (electromagnet in Einthoven String Galvanometer, see below) and a coil or wire designed to carry an electric current, the magnet and coil being so mounted that the passage of the current through the coil causes a deflection of either the coil or the magnet, as a result of the mechanical force with which the current and magnet act on each other. See *Electricity and Magnetism, Principles of.* Ordinary direct-current ammeters and voltmeters are operated on the same principle, but the term galvanometer is usually reserved for instruments designed for measuring relatively small currents, the deflection being read either by means of a telescope and scale or by means of a lamp and scale. In portable test set galvanometers the deflection of a pointer is read.

Moving-needle versus Moving-coil Galvanometers. — Galvanometers in which the moving element is the permanent magnet, in the form of a light needle, are called needle galvanometers, whereas those in which the moving element is the coil are called moving-coil galvanometers. The former type of galvanometer is required when extreme sensitiveness is desired, but cannot as a rule be used in a commercial laboratory, on account of the disturbing influences of the magnetic fields due to the lighting and power circuits in the laboratory and in neighboring buildings. Railway circuits, even though a mile or more away, may produce a disturbing field sufficient to render impossible the use of a sensitive needle galvanometer. For ordinary laboratory work, however, the moving-coil galvanometer can be made sufficiently sensitive, and since the permanent magnets used to produce the controlling field can be made very strong, the effect of stray fields can be rendered relatively negligible.

Astatic Galvanometer. — The disturbing effect of stray magnetic fields on a needle galvanometer can be partially prevented by the use of two sets of stationary coils and two needles, or the equivalent, the two needles being so arranged that any external field will produce opposing torques, and the coils so connected that their torques are additive. The Broca galvanometer, Fig. 1, described below, is a modern type of astatic instrument.

Damping and Logarithmic Decrement. — Due to the mechanical friction to motion and the induced currents set up in the adjacent metal or coils of the instrument as a result of the motion of the moving element, successive swings of the moving element when it is once set in motion decrease in amplitude. This effect is known as damping. Successive swings from the zero or equilibrium position decrease approximately in geometric ratio. Hence the ratio of the logarithm of one swing to the logarithm of the next swing, to the other side of the zero, is approximately a constant. This constant, which is a measure of the damping, is called the logarithmic decrement of the instrument.

Ballistic Galvanometer. — A ballistic galvanometer is one in which the moving element has a relatively long period and small damping. It can be shown that when a quantity of electricity Q is discharged through such a galvanometer in an interval of time *very short* compared with the period of the galvanometer, then the first throw or swing of the moving element is approximately proportional to the quantity of electricity Q. Such an instrument therefore serves as a very convenient means of measuring the capacity of a condenser (*see Capacity and Charging Current; Condensers, Electric*) as well as for measuring the quantity of electricity discharged through a circuit by transient induced electromotive forces (*see Magnetic Testing*).

Effect of External Resistance on Damping. — Since the damping of a galvanometer is due in part to the currents induced in the coils of the instrument by the motion of the moving element, and since these currents depend upon

the total resistance in series with these coils, it follows that the damping depends upon the constants of the external circuit. In particular, a low-resistance shunt around the galvanometer terminals may reduce the damping very considerably. Consequently, in any measurements involving the comparison of initial throws or swings of the moving elements, care must be taken that the same external resistance is kept in the external circuit, or that a universal shunt (*see Shunts*) connected to give a high multiplying power (100 or more) be used.

Dead-beat Galvanometers. — When the damping of a galvanometer is very large, the free motion of the moving element ceases to be periodic, and for a constant current sent through the coils the moving element swings out to its new position and comes to rest without oscillation. Such an instrument is said to be dead-beat. This dead-beat feature is very desirable when steady deflections are to be observed; it may be obtained mechanically by mounting a light vane of mica on the moving element, or by placing a solid piece of metal close to the moving element so that the motion of the latter will induce currents in the metal.

Aperiodic Galvanometer. — When the damping is *just sufficient* to render the instrument dead-beat, the galvanometer is said to be aperiodic.

Alternating-current Galvanometers. — The ordinary type of galvanometer cannot be used for measuring alternating currents, since the twisting moment depends upon the *direction* of the current. An ordinary galvanometer may, however, be used indirectly by connecting in series with it a thermo-couple, the latter being heated by a coil carrying the alternating current to be measured; this is the principle of Duddell's thermo-galvanometer. The "twisted-strip" galvanometer in which the deflection is caused by the untwisting of a strip, due to the heating action of the current, has also been used as an alternating-current galvanometer. These instruments, however, are both decidedly inferior to the Einthoven "vibration" galvanometer (Fig. 3) described below.

Tangent and Sine Galvanometers are of historical interest only, and need not be described here.

Sensitiveness of Galvanometers. — The sensitiveness or deflectional constant of a galvanometer may be defined as the scale deflection in millimeters produced by a current of one micro-ampere passing through the galvanometer coil, the scale being at one meter distance from the mirror; or, if the instrument has a scale attached, as the number of smallest scale divisions per micro-ampere, it may also be stated in terms of the potential difference in micro-volts, which must be applied to the terminals of the galvanometer to produce unit deflection, or as the deflection in millimeters, at meter distance of scale, per micro-volt on the terminals. The sensitiveness of a galvanometer must be accompanied by good *zero-keeping quality*.

TYPICAL MODERN GALVANOMETERS. — Only a few typical forms of modern galvanometers can be described here.

The Broca Galvanometer. — This galvanometer is one of the best of the moving-needle type. It owes its sensitiveness and freedom from disturbance by external magnetic fields to the unique construction of its system. This system, shown in Fig. 1, consists of two vertical steel wires placed side by side and magnetized to have consequent poles at their centers.

This construction makes a system that is very astatic and though magnets of considerable size are used, they are placed so close together that the system has a very small moment of inertia. A small mirror is located below the magnet system and below this an aluminum damping vane that moves in a chamber, the size of which can be varied, thus changing the damping. The whole system is suspended by a quartz fiber which serves as a control for the system, although

the main control is obtained by a movable permanent magnet on the base of the instrument. The stationary coils are made interchangeable and removable and vary in resistance from 10 ohms to 1000 ohms per pair.

Either lamp and scale or telescope and scale can be used to read the deflections of this galvanometer. In the latter case the scale must be brilliantly illuminated, owing to the small size of the mirror.

The resistance of this galvanometer can be varied by connecting the fixed coils in parallel or series or by substituting coils of different resistances. To vary the damping two rods on either side of the instrument case are pushed in

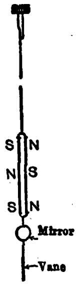

Fig. 1. Broca Galvanometer System

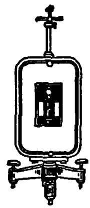

Fig. 2. D'Arsonval Galvanometer

or pulled out as required, to increase or decrease the size of the damping chamber. The period is changed by changing the position of the control magnet in reference to the system.

In the following table is given the sensitiveness of the instrument for various periods and resistances.

Resistance of coils in series in ohms	Period in seconds	Deflection in mm. at 1 m.	
		For 1 micro-ampere	For 1 micro-volt
10.9	8	218	19.9
107	12	1190	11.1
935	11	2450	2.62

D'Arsonval Galvanometers. — For the great majority of electrical measurements requiring galvanometers the D'Arsonval types, of which there are many forms, are the most satisfactory. Fig. 2 shows a typical form of construction, suitable either for mounting on the wall or on a tripod. This galvanometer has for its frame an iron casting which also serves as the permanent magnet and to hold the upper suspension tube. In the wall type this magnet casting is attached to a backboard holding the telescope and scale and the soft-iron core.

The coil is wound with copper wire, free from iron and suspended from above by a wire or strip of phosphor bronze, silver or steel, which also serves as one terminal of the coil. The other terminal is in the form of a spiral of phosphor bronze or silver strip brought off from the bottom of the coil. The coil carries a light mirror and the entire moving system is visible through a large window in

a metal plate that covers the front of the magnet casting, this front plate being removable. The deflection is read by a telescope and scale, the scale curved so that the scale reading will be closely proportional to the deflection.

The following table gives the approximate sensitiveness of galvanometers of this type for different coil resistance and period.

MILLIMETERS PER MICRO-AMPERE

Periods in seconds	Galvanometer resistance			
	50 ohms	300 ohms	500 ohms	1000 ohms
7	50	150	200	300
10	100	300	450	600
12	150	500	650	800

D'Arsonval galvanometers of a slightly different form, having a sensitiveness 50 per cent greater than the above, are on the market. Portable galvanometers, or ammeters of high sensitiveness (0.5 to 10 micro-amperes per smallest scale division) are also used in connection with thermo-couples and for measuring insulation resistance.

Einthoven String Galvanometer. — The Einthoven string galvanometer, a diagrammatic view of which is shown in Fig. 3, is essentially a moving-coil galvanometer, though the conductor which moves is but a single filament. *NS* are the poles of a powerful electromagnet, and the fine conducting "string" *AB* stretched in the narrow air gap between the poles forms the moving element. When a current is passed through this conducting string, it deflects at right angles to the field of the electromagnet as indicated by the solid arrows. This deflection is observed by means of a microscope or by projecting an enlarged image of the string on a screen by means of a projection lantern, or the deflection may be recorded on a photographic plate.

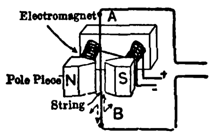

Fig. 3. Einthoven String Galvanometer

The electromagnet is relatively large and the pole faces are so shaped that an exceedingly high flux density is secured in the narrow air gap in which the string is stretched. The magnetic circuit is always fully saturated so that small variations in the exciting current do not affect the flux density in the air gap. The string, which may be an extremely fine silver wire or a silvered quartz fiber, is held under tension, which is adjustable by means of a micrometer screw. The resistance may vary from 5 ohms to 10,000 ohms, depending on the material of the string. The period depends on the tension on the string and may be reduced to less than 0.01 second or may be increased to 8 or 10 seconds with corresponding increase in sensibility.

The following table gives the characteristics of some Einthoven string galvanometers built by the Cambridge Scientific Instrument Company, when used on direct current.

Einthoven Galvanometer as an A-C. Detector, or Vibration Galvanometer. — If an alternating current is sent through the string and the tension on the latter is adjusted so that the free period of the string is the same as the period of the current, then the string will be set in vibration, the amplitude of the vibration depending upon the strength of the current. Consequently when the instrument is thus tuned, it may be used as a detector of extremely

CHARACTERISTICS OF EINTHOVEN STRING GALVANOMETERS

Material of string	Diameter of string	Resistance in ohms	Period in seconds	Magnifying power of microscope	Deflection* in mm.	
					Per micro-amp.	Per micro-volt
Silver wire.......	0.02 mm.	4.7	......	500	4.4	0.94
Silvered quartz fiber........	0.002 mm.	20,000	......	500	62,500	3.13
	0.003 mm.	6,600	......	650	333,000	50.5
	0.002 mm.	5,800	0.008	750	30	0.005
	0.002 mm.	3,890	0.005	750	9.7	0.003

* These are apparent deflections as observed through the microscope. For example, in the case of the galvanometer having the constants given in the third line, the actual deflection is $333000/650 = 512$ mm. per micro-ampere. An apparent deflection of about ⅛ mm. can be detected by the eye, consequently with this particular galvanometer a current of $10^{-6}/3 \times 333000 = 10^{-12}$ amperes, approximately, may be detected.

minute alternating currents. When thus used the instrument is capable of detecting an alternating current of 10^{-12} amperes, effective value.

Marine Galvanometers. — Any galvanometer that will give deflections that are not affected by the rolling of a ship and consequently can be used on shipboard may be called a marine galvanometer. A common form of marine galvanometer is of the D'Arsonval type with the coil held by suspensions, both above and below, that are stretched under considerable tension.

The moving system of the galvanometer is carefully balanced, so that a 30-degree inclination will not cause a deflection of more than 3 mm. with the scale at 1 meter distance. It has a very stable zero and a sensibility of 10 to 20 micro-amperes per smallest scale division with a 3-second period.

USE AND CALIBRATION OF GALVANOMETERS. — Galvanometers, other than ballistic, are used in engineering work primarily as current *detectors* in various bridge (q.v.) and potentiometer (q.v.) measurements, and therefore careful calibration is usually unnecessary. In order to determine the degree of precision of such measurements, however, the sensitiveness of the galvanometer must be known. This may be determined by connecting in series with a battery of known e.m.f. a fairly high resistance, and connecting the terminals of galvanometer across a known small fraction of this resistance. If the galvanometer resistance is known or previously measured, the current through the latter may then be calculated by Kirchhoff's laws (*see Electricity and Magnetism, Principles of*), and consequently the millimeters deflection per micro-ampere determined. If the sensitiveness of the galvanometer is too great for any particular measurement, it may be reduced by properly shunting it (*see Shunts*).

Calibration of Ballistic Galvanometer. — The ballistic galvanometer is frequently used for capacity measurements and for the determination of the magnetization curves of samples of iron or steel (*see Magnetic Testing*). One method of calibration is to charge a standard condenser to a known voltage, and discharge it through the galvanometer, noting the deflection, and repeating the test for several known voltages. As the capacity of ordinary standard condensers is dependent upon the time of charging (*see Condensers, Electric*), this method is not very accurate.

Use of Standard Solenoid. — A better method is to use a standard solenoid. Such a solenoid should have a length about 50 times its diameter. A standard used in a number of experiments conducted under the auspices of the Standardization Committee of the American Society for Testing Materials is made of 1520 turns of No. 18 A.W.G. double-cotton-covered copper wire carefully wound in a single layer upon a cylindrical core of red fiber approximately 75 inches long and 1.5 inches in diameter. (A convenient way of winding such a coil uniformly is to cut a shallow thread in the core of such a pitch that the wire when wound in the groove between the threads will lie up snug.) A secondary coil of 2000 turns of No. 36 A.W.G. double-silk-covered wire was wound in 2 layers over a length of 6 inches, at the middle of this coil.

Connect the primary coil of this solenoid in series with an adjustable resistance, reversing switch and source of constant e.m.f. Connect the secondary coil in series with the galvanometer. Let

n_1 = the number of turns *per inch length* of the primary coil,
I_1 = the strength of the current in amperes in the primary coil,
N_2 = the number of turns in the secondary coil,
R = the total resistance in ohms of the secondary coil, galvanometer and any extra resistance which may be in the secondary circuit,
A = the area in square inches of the mean cross-section of the primary coil.

Then if the current I in the primary coil is reversed a quantity of electricity

$$Q = \frac{2.54 \times 8\pi}{10^9} \frac{n_1 I_1 A N_2}{R} \quad \text{coulombs}$$

$$= 0.0638 \frac{n_1 I_1 A N_2}{R} \quad \text{microcoulombs}$$

is discharged through the galvanometer. Hence, by calculating Q and noting the galvanometer swings when currents of various strengths are reversed in the primary coil, a curve can be plotted giving the quantity of electricity corresponding to a swing of any value; such a curve will be approximately a straight line.

COSTS. — A Broca galvanometer costs from \$40 to \$50 depending upon its sensitiveness. A D'Arsonval galvanometer costs from \$18 to \$100, including telescope and scale. An Einthoven galvanometer costs from \$400 to \$500.

[H. PENDER AND H. R. RANKEN.]

GAS. — (*See also Gas Engines; Gas Producers.*) The word gas in its most general sense means a substance which is capable of indefinite expansion. The word is also used in a restricted sense to mean any mixture of gases suitable for illumination or for fuel. It is in this sense that the word will be used in this article.

Gas is usually measured in thousands of cubic feet, at 60° F. and at a pressure of 30 inches of mercury. The term "permanent" or "fixed" gas is used to designate a gas which will not precipitate any of its constituents when cooled.

KINDS OF GAS. — In addition to natural gas, which exists in limited quantities, in restricted localities (in this country, chiefly in western Pennsylvania, West Virginia, Ohio, Indiana, Kansas, Texas and California), there are four types of manufactured gas. These various types all contain the same constituent gases, but in different proportions, depending upon the process of manufacture and the fuel from which they are made. Gas may be made from practically any kind of solid or liquid fuel, but coal is the fuel usually employed.

Coal-Gas. — This name is given to the mixture of permanent gases resulting from the distillation in closed retorts of the volatile matter in coal. The heavy hydrocarbons and various impurities are extracted by cooling and "washing" the gas and passing it through purifiers containing hydrated lime or sesquioxide of iron. The residue left in the retorts is coke; the condensed hydrocarbons form coal-tar; ammonia, sulphur compounds and cyanogen are absorbed in the washers and purifiers; all these by-products are of value.

Coal-gas is used chiefly for illumination, but in this country carburetted water-gas (see below) is more extensively employed for this purpose. Coal-gas is seldom used for power purposes on account of its high manufacturing cost as compared with producer-gas (see below), which, though unsuitable for illumination, makes a very satisfactory fuel for gas engines.

Water-Gas. — This name is given to the mixture of permanent gases resulting from the reactions which take place when steam is passed through a body of coal, coke or charcoal heated to redness or beyond, the hot gas being condensed and purified in much the same manner as coal-gas. The chief reaction in the formation of this gas is the decomposition of the steam by the heated carbon, forming hydrogen and carbon monoxide, the reaction being $C + H_2O = CO + 2\,H$. This reaction is a cooling process, hence the production of water-gas is intermittent, consisting of two stages: (1) the "blowing up" or heating the fuel in the producer by blowing air into it, producing CO_2 by the reaction $C + 2\,O = CO_2$, and (2) the production of water-gas by blowing steam through the fuel, the supply of air having been shut off. Water-gas is generally made from anthracite coal and contains not only hydrogen and carbon monoxide, but also small amounts of oxygen, nitrogen and light hydrocarbons. Pure water-gas is not suitable for illumination, since it is deficient in the heavy hydrocarbons which render coal-gas a good illuminant. This defect is readily supplied by adding naphtha vapor to the water-gas as it comes from the producer and superheating the mixture thus formed; the naphtha vapor and the superheated steam in the gas react to form permanent gases of the hydrocarbon group. Water-gas thus heated is called "carburetted water-gas" and forms an excellent illuminant. In this country, by far the greater proportion of illuminating gas is carburetted water-gas. Water-gas, pure or carburetted, is seldom used for power purposes, on account of its high cost.

Siemens Gas. — This name is given to the mixture of permanent gases resulting from the chemical reactions which take place when air is blown or drawn into a deep bed of coal. At the bottom of the bed, where the air is in excess, CO_2 is formed and this is reduced on passing through the upper part of

the bed to CO by the reaction $CO_2 + C = 2\,CO$. The resulting gas also contains hydrogen, resulting from the reaction between the moisture in the coal and the hot carbon, this reaction being the same as in the production of water-gas. The nitrogen of the air is also present in the gas, forming more than half its volume, thereby making a very dilute or "lean" gas. This process has been superseded by the producer-gas process described below.

Producer Gas. — This name is given to the mixture of permanent gases resulting from the chemical reactions which take place when both steam and air are blown through a bed of hot coals. The gas is essentially a mixture of water-gas and Siemens gas. The process is a continuous one, enough air being supplied with the steam to maintain the producer bed at the proper temperature, thus eliminating the "blowing up" operation in the water-gas process; also, due to the presence of the steam and the reactions which take place between it and the carbon, the proportion of hydrogen is increased and the proportion of nitrogen decreased, thus making a gas "richer" than Siemens gas. The exact composition of producer gas depends upon the kind of fuel used and the type of producer, of which there are numerous forms (*see Gas Producers*). The gas made in any particular form of producer is frequently called by the name or type of the producer, for example, "Mond gas," "Dowson gas," etc. Producer gas is used in power plants employing large gas engines; it is also used for firing ceramic kilns and metallurgical furnaces, and, to a limited extent, for firing steam boilers.

The thoroughness with which the gas must be cleaned depends upon the purpose for which it is to be used. For gas-engine work, it is particularly important that no tar should be present. On this account, anthracite coal is frequently used for the production of the gas for this purpose, in spite of the relatively high cost of such coal.

Other Kinds of Gas. — "Oil-gas" is a mixture of gases resulting from the vaporization of crude oil and superheating the vapor; it is used to improve the illuminating qualities of water-gas. "Coke-oven gas" is the gas formed as a by-product in coke ovens. Its properties are intermediate between those of coal-gas and Siemens gas; the composition of the gas, however, varies with the kind of coal and with the time, changing from the beginning to the end of the process. "Oil-water gas" is produced by the chemical reactions between steam and oil heated to a high temperature in closed retorts. The cost of manufacture is low where oil is cheap. "Blast-furnace gas" is a waste product of blast furnaces, and is a mixture of CO, CO_2 and N, the latter being the largest constituent. The relative proportions of CO and CO_2 vary with the conditions of the furnace. An average analysis of blast-furnace gas cooled to atmospheric temperature is 25 per cent CO, 10 per cent CO_2, 65 per cent N. Coke-oven gas, oil-water gas and blast-furnace gas are all suitable for use in gas engines.

CALORIFIC OR HEATING VALUE. — The calorific or heating value (*see Heat and Thermal Properties*) of a given quantity of gas is the heat energy developed by its complete combustion. In this country, the calorific value of a gas is usually expressed in B.t.u. per cubic foot, the volume being measured at 60° F. and at a pressure of 30 inches of mercury. The total heating value of the gas produced from a given quantity of coal is less than that of the coal (or other fuel) from which it is made. In the case of coal-gas, the fixed carbon in the coal is not "gasified," and, therefore, its calorific value contributes nothing to that of the gas. In the case of water-gas and producer-gas, the carbon in the coal is converted into carbon monoxide, but the heating value of carbon monoxide is less than that of the carbon in it, since this carbon is already partially oxidized. Heat energy is also required to distil the hydrocarbons in the coal and in addition there are losses due to radiation. The calorific value of pro-

ducer-gas made from a given quantity of coal varies from 55 to 85 per cent of the calorific value of the fuel from which it is made, depending upon the character of the fuel, the size of the producer and the manner of operating it.

EFFECTIVE OR NET HEATING VALUE. — The discharge from a gas engine is at a temperature considerably greater than the boiling point of water, and, consequently, the latent heat of condensation of the water vapor in the products of combustion is not available for the production of power, whereas in a calorimetric determination of the heating value of a gas this latent heat of condensation is included. The difference between the heating value, as determined by calorimetric measurement and the latent heat of condensation of the water vapor in the products of combustion, is called the effective or net heating value of the gas. The net heating value of producer-gas is usually about 5 per cent lower than the gross heating value.

COMPARISON OF DIFFERENT KINDS OF GAS. — The following table shows what may be considered the average composition (percentage by volume), weight, calorific value and moisture content of the different types of gases used for illumination and for fuel. It should be noted, however, that the characteristics of any particular gas may vary considerably from the figures given in the table, depending upon the quality of the coal used and the size and type of producer.

COMPARISON OF DIFFERENT KINDS OF GASES

Item	Natural gas	Coal-gas	Water-gas	Producer-gas	
				Anthracite	Bituminous
CO	0.50	6.0	45.0	27.0	27.0
H	2.18	46.0	45.0	12.0	12.0

GAS ENGINES AND OTHER INTERNAL-COMBUSTION ENGINES. — (*See also Gas; Gas Producers, Power Stations, Gas-Electric.*) An internal-combustion engine is an engine in which combustible gas, vapor, or oil is burned in a cylinder, generating a high temperature and high pressure in the gases of combustion, which expand behind a piston, driving it forward. (Rotary gas engines or gas turbines are still, 1914, in the experimental stage.)

Gas Engine. — A gas engine in its simplest form is similar to a reciprocating single-acting steam engine, comprising a cylinder, a piston, crank, flywheel, etc. The pressure to move the piston is obtained by exploding or burning with great rapidity a compressed mixture of air and combustible gas.

Oil and Gasoline Engines. — The lighter distillates of petroleum, such as gasoline, are easily vaporized at moderate temperatures, and a gasoline engine differs from a gas engine only in having an atomizer attached, for spraying a fine jet of the liquid into the air-admission pipe. With kerosene and other heavier distillates, or crude oils, it is necessary to provide some method of atomizing and vaporizing the oil at a high temperature, such as injecting it into a hot vaporizing chamber at the end of the cylinder, or into a chamber heated by the exhaust gases.

Diesel Oil Engine. — The distinguishing features of the Diesel engine are: It compresses air only, to a predetermined temperature above the firing point of the fuel. This fuel is blown as a cloud of vapor (by air from a separate small compressor) into the cylinder when compression has been completed, ignites spontaneously without explosion, solely by reason of the heat of the air generated by the compression, and burns steadily with no essential rise in pressure. The temperature of gases, developed and rejected, is much lower than with engines of the explosive type. The engine uses crude oil and residual petroleum products. Guarantees of fuel consumption are made as low as 8 gallons of oil (not heavier than 19° Baumé) for each 100 brake horse-power hours at any load between half- and full-rated load.

American Diesel engines are built for stationary purposes, in sizes of 120, 170 and 225 horse-power in three cylinders, and in "double units" (six cylinders) of 240, 340 and 450 horse-power. Much larger sizes have been built in Europe.

Alcohol Engines. — Due to the relatively high cost of alcohol, even when "denatured," alcohol engines are not yet in commercial use in this country.

CLASSIFICATION OF INTERNAL-COMBUSTION ENGINES. — Internal-combustion engines are classified as four-cycle and two-cycle engines, single- and double-acting engines, and single- and multi-cylinder engines.

Four-cycle Engines. — In what is known as a four-cycle engine, one ignition of gas takes place in one end of the cylinder every two revolutions of the flywheel, or every two double strokes. The following sequence of operations takes place during four consecutive strokes: (*a*) inspiration of a mixture of gas and air during an entire stroke; (*b*) compression during the second (return) stroke; (*c*) ignition at or near the dead-point and expansion during the third stroke; (*d*) expulsion of the burned gas during the fourth (return) stroke.

Fig. 1 is an indicator diagram of a four-cycle engine. *AB*, the lower line, shows the admission of the mixture, at a pressure slightly below the atmosphere on account of the resistance of the inlet valve. *BC* is the compression into the clearance space, ignition taking place at *C* and combustion with increase of pressure continuing from *C* to *D*. The gradual termination of the combustion

is shown by the rounded corner at D. DE is the expansion line, EF the line of pressure drop as the exhaust valve opens, and FA the line of expulsion of the burned gases, the pressure being slightly above the atmosphere on account of the resistance of the exhaust valve.

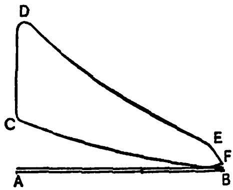

Fig. 1. Indicator Diagram of Four-cycle Engine

Two-cycle Engine. — In a two-cycle single-acting engine an explosion takes place with every revolution, or with each forward stroke of the piston. Referring to the diagram, Fig. 1, and beginning at E, when the exhaust port begins to open to allow the burned gases to escape, the pressure drops rapidly to F. Before the end of the stroke is reached an inlet port opens, admitting a mixture of gas and air from a reservoir in which it has been compressed. This mixture being under pressure assists in driving the burned gases out through the exhaust port. The inlet port and the exhaust port close early in the return stroke and during the remainder of the stroke BC the mixture, which may include some of the burned gas, is compressed and the ignition takes place at C, as in the four-cycle engine.

In one form of the two-cycle engine only compressed air is admitted while the exhaust port is open, the fuel gas being admitted under pressure after the exhaust port is closed. By this means a greater proportion of the burned gases is swept out of the cylinder. This operation is known as "scavenging."

Single- and Double-acting Engines. — These terms have the same significance as in the case of steam engines (q.v.). Comparatively few large engines are single-acting.

Multi-cylinder Engines. — In small multi-cylinder engines the cylinders are in "parallel," i.e., each has a separate piston connected to the crank shaft. In large engines two cylinders are frequently arranged in tandem. The term "twin cylinder" is used to designate two cylinders operating in parallel as contrasted with the "two-cylinder tandem" arrangement, in which the two cylinders are in "series." A "twin-tandem" engine has four cylinders in all, or two pairs of tandem cylinders.

RATING. — In contrast to steam prime movers the gas engine has a definite limit of power with the usual methods of governing and its economy improves until this limit is almost reached. This characteristic makes a maximum rating more significant than a normal rating with overload capacity. As ordinarily rated, however, engines can develop 10 to 15 per cent overload for brief periods and will care for momentary swings much greater. Due to their low mechanical efficiency (75 to 85 per cent) gas engines are preferably rated in terms of their brake horse-power instead of indicated horse-power.

Rating of Automobile Engines. — Automobile engines are single acting and as a rule multi-cylinder, the cylinders all being in parallel. The American Licensed Automobile Manufacturers Association have adopted the following arbitrary formula for the rating of automobile engines

$$\text{Brake horse-power} = \frac{D^2N}{2.5},$$

where D = diameter of each cylinder in inches, N = number of cylinders. This rating is usually referred to as the A.L.A.M. rating. It corresponds approximately to the actual brake horse-power when the piston speed is 1000 feet per minute and the mean effective pressure is 55 pounds per square inch.

The following ratings are derived from the formula:

Bore, in.	2½	3	3½	4	4½	5	5½	6
Bore, mm.	64	76	89	102	114	127	140	152
Horse-power, 1 cylinder	2½	3.6	4.9	6.4	8.1	10	12.1	14.4
Horse-power, 2 cylinders	5	7.2	9.8	12.8	16.2	20	24.2	28.8
Horse-power, 4 cylinders	10	14.4	19.6	25.6	32.4	40	48.4	57.6
Horse-power, 6 cylinders	15	21.6	29.4	38.4	48.6	60	72.6	86.4

DESIGN AND CONSTRUCTION. — Only a few of the more important features in the design and construction of internal-combustion engines can be noted here. See *Bibliography* at end of this article for references to various treatises on the subject.

Arrangement of Cylinders in Large Engines. — The number and arrangement of cylinders depends upon the space, the power required and the uniformity of rotation to be produced. Vertical-cylinder engines are built in sizes up to 750 horse-power. They require less floor space than the horizontal types but the superior mechanical properties of the latter warrant their selection when space economy is not important. The tandem double-acting arrangement is standard in horizontal engines. As it is not practicable to develop more than 1500 horse-power in a single cylinder, engines of the largest sizes are twin, tandem, double-acting.

Cooling is one of the most important problems of gas-engine design. In the small sizes provision for air cooling or a simple water jacket about the cylinder walls suffices, but the large sizes require the cooling of the piston, piston rod, and valve stems. The superficial area of the cylinders increases less rapidly than their cubical contents and this fact tends to aggravate the cooling problem as the size of the cylinders is increased. Cooling is more difficult with rich gases than with lean. One practical result of these difficulties is found in the fact that engines of large capacity are little if any cheaper per horse-power than small ones and that maintenance is apt to be proportionately larger.

Ignition. — The "hot-tube" method of igniting the compressed mixture of gas and air in the cylinder is practically obsolete, and electric systems are used instead. Of these the "make-and-break" and the "jump-spark" systems are in common use. In the former two insulated contact pieces are located in the end of the cylinder, and through them an electric current passes while they are in contact. A spark coil is included in the circuit, and when the circuit is suddenly broken at the proper time for ignition, by mechanism operated from the valve-gear shaft, a spark is made at the contacts, which ignites the gas. In the "jump-spark" system two insulated terminals separated about 0.03 inch apart are located in the cylinder, and the secondary or high-tension current of an induction coil causes a spark to jump across the space between them when the circuit of the primary current is closed by mechanism operated by the engine.

In some oil engines the mixture of air and oil vapor is ignited automatically, by the temperature generated by compression of the vapor, in a chamber at the end of the cylinder, called the vaporizer, which is not water-jacketed and therefore is kept hot by the repeated ignitions. Before starting the engine the vaporizer is heated by a Bunsen burner or other means.

Timing. — By adjusting the cam or other mechanism operated by the valve-gear shaft for causing ignition, the time at which the ignition takes place, with reference to the end of the compression stroke, can be regulated. The mixture

is usually ignited before the end of the stroke, the advance depending upon the inflammability of the mixture and on the speed of the engine.

Governing. — Two methods of governing the speed of an engine are in common use, the "hit-and-miss" and the throttling methods. In the former the engine receives its usual charge of air and gas only when the engine is running at or below its normal speed; at higher speeds the admission of the charge is suspended until the engine regains its normal speed. One method of accomplishing this is to interpose between the valve rod and its cam or other operating mechanism, a push rod, or other piece, the position of which with reference to the end of the valve rod is controlled by a centrifugal governor so that it hits the valve rod if the speed is at or below normal and misses it if the speed is above normal.

The throttling method of regulating is similar to that used in throttling steam engines; the quantity of mixture admitted at each charge being varied by varying the position of a butterfly valve in the inlet pipe. Cut-off methods of governing are also used, such as varying the time of closing the admission valve during the suction stroke, or varying the time of admission of the gas alone, or "quality regulation."

Lubrication of cylinders is best provided by a time force-feed system injecting oil between the piston rings at dead-center positions. The supply should be closely regulated, as an excess carbonizes on the cylinder walls and becomes a source of trouble. Bearings are commonly ring-oiled or flooded.

Starting Devices. — In large engines starting is now universally accomplished by compressed air. In some small stationary engines an explosive cartridge is inserted into the cylinder head and set off by percussion.

Self-starting devices, using compressed air or a small electric motor and storage battery, are coming into extensive use for starting automobile engines.

Speeds. — Small gasoline engines are usually designed for speeds of from 300 to 1000 revolutions per minute, Large gas engines, for central-station service, usually have speeds about as follows:

100 h.p.	275 rev. per min.
300 h.p.	200 rev. per min.
500 h.p.	150 rev. per min.
1000 h.p.	100 rev. per min.

POWER DEVELOPED BY AN INTERNAL COMBUSTION ENGINE. — In order to calculate the power developed by an internal-combustion engine it is necessary to know the mean effective pressure in the engine cylinder, the dimensions of the cylinder and either (1) the length of stroke and number of explosions per minute, or (2) the piston speed and number of explosions per revolution.

Mean Effective Pressure. — The mean effective pressure can be obtained from the indicator diagram (*see Steam Engines*), or if a test diagram is not available the mean effective pressure either has to be assumed from a knowledge of that found in other engines of the same type and working under the same conditions as those of the design, or it may be calculated from the ideal air diagram and modified by the use of a coefficient or diagram factor depending on the kind of fuel used and the compression pressure.

The following figures are given by C. P. Poole as a rough approximate guide to the mean effective pressures obtained with different fuels in a four-cycle engine. In a two-cycle engine the mean effective pressure of the pump diagram should be subtracted. The delivery pressure is usually from 4 to 8 pounds per square inch above the atmosphere, and the corresponding mean effective pressure of the pump about 3.8 to 7.

PROBABLE MEAN EFFECTIVE PRESSURE, POUNDS PER SQUARE INCH, FOUR-CYCLE ENGINES

Kind of fuel	Compression pressure	Engine horse-power						
		5	10	25	50	100	250	500
Anthracite Producer gas	100	..	55	60	65	70	75	80
	130	..	65	70	75	80	85	90
	160	..	..	..	80	85	90	90
Mond Producer gas	100	..	..	60	65	65	70	75
	130	..	65	65	70	75	80	85
	160	..	..	75	80	85	90	90
Natural and Illuminating gas	65	..	60	65	70	80	85	..
	100	..	75	80	90	90	95	100
	130	..	..	..	..	100	105	110
Gasoline vapor	65	70	75	80	85	..	..	..
	100	85	90	90	95	..	..	..
Kerosene spray	65	50	55	60	65	..	..	..
	115	70	75	80	85	..	..	..

Number of Explosions per Revolution. — The number of explosions per revolution depends upon the type of engine, as given in the accompanying table.

Formulas for Horse-power Output. — Let

p = mean effective pressure, lb. per sq. in.
d = diameter of cylinder bore, inches,
N = number of revolutions per minute,
e = total number of explosions per revolution,
S = piston speed, feet per minute,
L = length of stroke, feet,
ϵ = mechanical efficiency, as a fraction,
P_i = indicated horse-power.

Type of engine	Explosions per rev. per cylinder
Single-acting, 4-cycle..	0.5
Single-acting, 2-cycle..	1.0
Double-acting, 4-cycle.	1.0
Double-acting, 2-cycle.	2.0

Then

$$P_i = \frac{pLd^2eN}{42{,}000} = \frac{pd^2eS}{84{,}000}.$$

The brake horse-power is

$$\text{Brake h.p.} = \epsilon P_i.$$

The brake horse-power is frequently expressed by the formula

$$\text{Brake h.p.} = Cd^2,$$

where $C = pe S\epsilon/84{,}000$ is called the "engine constant." For $\epsilon = 0.84$ and 2 explosions per revolution the values of C for various mean effective pressures are as follows:

VALUES OF *C* FOR 2 EXPLOSIONS PER REVOLUTION

M.E.P., lb. per sq. in.	Piston speed, feet per minute					
	500	600	700	800	900	1000
50	0.50	0.60	0.70	0.80	0.90	1.00
60	0.60	0.72	0.84	0.96	1.08	1.20
70	0.70	0.84	0.98	1.12	1.26	1.40
80	0.80	0.96	1.12	1.28	1.44	1.60
90	0.90	1.08	1.26	1.44	1.62	1.80
100	1.00	1.20	1.40	1.60	1.80	2.00
110	1.10	1.32	1.54	1.76	1.98	2.20

These values of *C* apply to 4-cylinders, 4-cycle, single-acting, to 2-cylinders, 2-cycle, single-acting, and to 1-cylinder, 2-cycle, double-acting. For single cylinders, 4-cycle, single-acting, divide by 4; for single cylinders, 4-cycle, double-acting, or 2-cycle, single-acting, divide by 2.

TESTING INTERNAL-COMBUSTION ENGINES. — The test of a gas or oil engine includes the measurement of its power by a friction brake, of the number of cubic feet of gas or pounds of oil used per brake horse-power hour, and of the calorific value of the gas or oil. In connection with the tests indicator diagrams may be taken, the air supply and the jacket cooling water may be measured, the exhaust gas analyzed, the temperatures of air, water and gas taken, and a heat balance calculated showing the thermal efficiency and the several sources of loss of energy. For details see *Code of 1914 of the A.S.M.E.*

EFFICIENCY AND FUEL CONSUMPTION. — The thermal efficiency of an internal-combustion engine is considerably higher than that of the best reciprocating engine or steam turbine; its mechanical efficiency is lower, ranging from 70 to 85 per cent as against 90 to 95 per cent for a high-class reciprocating engine and 92 to 97 per cent for steam turbines.

Thermal Efficiency. — The conditions which appear to give the highest thermal efficiency in gas and oil engines are: (1) high temperature of cooling water in the jackets; (2) high pressure at the end of compression; (3) lean mixture; (4) proper timing of the ignition; (5) maximum load. The higher economy of a lean mixture may be due to the fact that high compressions may be used with such a mixture, while with rich mixtures high-compression pressures cannot be used without danger of preignition.

Other things being equal, the hotter the walls of the cylinder the less heat is transferred into them from the hot gases, and therefore the higher the efficiency. Cool walls, however, allow of higher compression without preignition, and high compression is a cause of high efficiency. Cool walls also tend to give the engine greater capacity, since with hot walls the fuel mixture expands more on entering the cylinder, reducing the weight of charge admitted in the suction stroke.

Distribution of Heat Losses. — The heat losses are: (1) the heat carried away in the jacket water, (2) that carried away in the waste gases, and (3) that lost by radiation. The relative amounts of these three losses vary greatly, depending on the size of the engine and on the amount of water used for cooling. Carpenter and Diederichs quote the following,

Ratio of compression	R.p.m.	M.E.P., lb. per sq. in.	Ratio air to gas	Heating value of charge, B.t.u.	Work done by 1 B.t.u., ft. lb.	Exhaust temp., deg. F.	Distribution of heat losses, per cent		
							Work	Jacket water	Exhaust
2.67	187	54.3	7.11	18.5	140	1022	18.0	51.2	30.8
2.67	247	51.5	7.35	17.4	141	1137	18.1	45.6	36.3
4.32	187	69.3	7.43	17.0	190	867	24.4	53.8	21.8
4.32	247	65.2	7.40	16.8	184	992	23.7	49.5	26.8

showing that the distribution of the heat losses varies with the rate of compression and with the speed.

Over-all Efficiency and Fuel per Brake Horse-Power. — The over-all efficiency of internal-combustion engines is the product of the thermal efficiency by the mechanical efficiency. A more convenient expression is

$$\text{Over-all efficiency} = \frac{2546}{HQ} \quad \text{as decimal fraction}$$

where H = heat of combustion, B.t.u. in one cubic foot, and Q = number of cubic feet of gas supplied per brake horse-power hour. In the case of a liquid fuel it is more convenient to take H = heat of combustion, B.t.u. per pound, and Q = pounds of liquid supplied per brake horse-power hour. See articles on *Gas and Fuels*. The product HQ in either case is the number of B.t.u. per brake horse-power.

In Fig. 2 are given the results of tests on several internal-combustion engines using different kinds of fuels, and also, for comparison, the performance of three steam turbines. These curves were supplied by Prof. W. E. Wickenden. These curves bring out very strikingly the relatively poor performance of internal-combustion engines at light loads.

Coal per Brake Horse-power Hour. — Figures giving the coal consumption of a producer per brake horse-power hour of the gas engine supplied from it are of little value unless the type of producer and type of engine as well as the quality of the coal are stated. Let H = B.t.u. per pound coal, e_1 = efficiency of producer (*see Gas Producers*), e_2 = over-all efficiency of gas engine. Then

$$\text{pounds coal per brake horse-power hour} = \frac{2546}{He_1e_2}.$$

For example, if the heating value of the coal used is 14,000, the over-all efficiency of the gas engine 30 per cent and the efficiency of the producer 80 per cent, then $2546/14{,}000 \times 0.3 \times 0.8 = 0.76$ pound coal will be required per brake horse-power hour. Figures as low as 0.7 pound coal per brake horse-power hour have been obtained, but they are exceptional.

GAS AND OIL ENGINE TROUBLES. — Among the causes of troubles are: the variable composition of the fuel; too much or too little air supply; compression ratio not right for the kind of fuel; ignition timer set too late or too early; preignition; backfiring; electrical and mechanical troubles with the igniting system; carbon deposits in the cylinder and on the igniting contacts.

COST OF GAS ENGINES. — Differences in the ratings of gas engines, the partial development of the art and the close competition of builders make

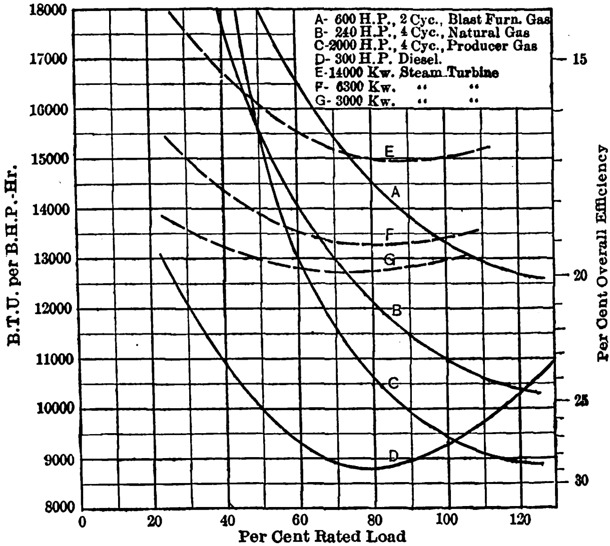

Fig. 2. Fuel Consumption of Gas and Oil Engines

costs quite variable. The following methods of estimating are derived from a number of installations and probably represent average conditions for electrical generation. (*W. E. Wickenden.*) Let P = brake horse-power rating; then

50 to 125 horse-power, cost in dollars: ....400+40 P
125 to 250 horse-power, cost in dollars.......2500+20 P
250 horse-power and larger, cost in dollars... 32 P

[Wm. Kent.]

GAS LIGHTING. — (*See also Gas; Gas Producers; Illumination, Laws of.*) Illuminating gases are rated in terms of "calorific value," expressed in B.t.u.'s per cubic foot, and in "illuminating power," or the candle-power of a standard luminous flame burner, in its most efficient state, consuming 5 cubic feet of the given gas per hour. Measurements of volume are reduced to standard conditions of temperature and pressure, viz., 60° F., and a 30-inch barometric height. Gas pressures are sometimes stated in atmospheres and in pounds per square inch, but more commonly by the inches of water manometer column which the gas sustains against atmospheric pressure (*see Units and Conversion Factors*). The supply pressure ranges from 1.5 to 4 inches in low-pressure systems and from 40 to 60 inches in high-pressure systems. Most of the gas systems in the United States are of the low-pressure type, but high-pressure systems are common in Europe. The chief commercial varieties of gas and their more important properties are as follows:

Coal Gas, produced by distillation from bituminous coal, consists chiefly of hydrogen, methane and richer hydrocarbons. It varies greatly in quality with the grade of coal and the stage of distillation. Values of 16 candle-power and 600 B.t.u.'s are representative of the usual commercial supply. The use of coal gas is diminishing.

Water Gas, produced by the reaction of steam and incandescent coal or coke, consists chiefly of hydrogen and carbon monoxide, and is usually enriched with oil gas to raise its calorific and luminous value. The properties of water gas supplied in different cities range from 18 to 22 candle-power and from 580 to 700 B.t.u.'s per cubic foot. Many plants supply a mixture of coal gas and water gas.

Oil Gas is a mixture of rich hydrocarbon gases produced by "cracking" petroleum oils by heat. Its candle-power is from 40 to 60 and its calorific value 1200 B.t.u.'s or more. On account of its richness oil gas is often diluted with air or mixed with water gas for commercial delivery.

Pintsch Gas is a type of oil gas stored under a pressure of 150 pounds per square inch in steel tanks for self-contained and portable systems of lighting. It is rated at approximately 900 B.t.u. and 36 candle-power. An essential feature of the Pintsch system is an automatic reducing valve which supplies the gas at a constant low pressure adapted to flame and mantle illuminants.

Acetylene, produced by the reaction of water and calcium carbide, is a simple rich gas with a rating of about 1470 B.t.u.'s and 240 candle-power. For use in portable and self-contained systems acetylene is dissolved in acetone under a pressure of about 150 pounds per square inch. The usual container has a storage capacity of 10,000 volumes at this pressure.

Gasoline-air Gas is a mixture of air with gasoline vapor produced by forced evaporation. The generator commonly used comprises a blower operated by weights or water power, a carburretor and a mixing chamber. In the most widely used type of carburretor air is forced through sheets of cotton cloth which dip in gasoline and a rich mixture is produced. In the mixer the gas is diluted with air to a mixture containing from 2 to 5 gallons of gasoline to 1000 cubic feet, which is well above the explosive limit. Self-contained lamps in which the fuel mixture is locally generated by heat from the lamp have a wide use in street lighting. The luminous value of this gas in flames is very low, but it is well adapted to incandescent burners.

Natural Gas consists chiefly of methane, has a calorific value of about 1000 B.t.u.'s and little luminous value in open flames. It is excellently adapted to incandescent burners.

PERFORMANCE OF FLAME ILLUMINANTS. — Light from a flame is due to minute incandescent carbon particles liberated from the gas by heat. The highest efficiency is obtained when the migration of these particles is slow; hence the pressure at the flame should not exceed two inches of water and the flame should be set but little above the smoking point. The horizontal light distribution from flames is sensibly uniform. The spherical reduction factor ranges from 85 to 92.5 per cent, depending on the occlusion of light by the burner. The batswing and fishtail burners used with ordinary gas should give fully 90 per cent of the rated illuminating power of the gas when properly adjusted. Acetylene is commonly burned in duplex burners with air holes giving slight pre-aeration. The usual one-foot acetylene burner gives 40 candle-power.

INCANDESCENT MANTLES AND BURNERS. — The incandescent or Welsbach mantle is the ashy residue of a woven structure of vegetable fibre, such as cotton, ramie or artificial silk, impregnated with oxides of cerium and thorium, with traces of other rare earths. The strength of mantle varies greatly with the material and weave of the fibrous base. Its luminous properties depend on the purity and proportions of the oxides used. Mantles are graded in quality chiefly by strength to resist shock, but the better grades are greatly superior in the maintenance of their candle-power.

The incandescent burner is made in two general types, upright and inverted. Each has a Bunsen tube with adjustable gas cock and air inlet. The entraining action and flame projection of the upright type is fairly self-regulating for a wide range of gas pressure and consumption. The inverted type admits of a narrow range of adjustment. The conditions required to obtain the highest efficiency from mantle burners are: (*a*) all gas and air ports must be clear and adjusted to give the proper air-gas mixture and best projection pressure at the flame; (*b*) the flame should burn at the highest possible temperature and the mantle should be completely immersed in the hottest or outer zone of the flame.

Performance of Mantle Burners. — Candle-power and efficiency ratings are based on lamps fitted with new mantles and tuned up by a fitter's adjustment to the most efficient conditions. The average performance of mantle burners in service is always somewhat below the rated values and depends to a marked degree on maintenance conditions. Service deterioration is due to (*a*) the fouling of the burner with dust, (*b*) the improper adjustment of air and gas ports, (*c*) the shrinkage of mantles and loss of their active materials, and (*d*) the collection of dirt on glassware. Low-grade mantles show very rapid deterioration, often amounting to 40 per cent in 500 hours. R. F. Pierce (*Trans. Ill. Eng. Soc., Vol. VII, p. 686*) reports from reliable tests under favorable conditions the inherent deterioration in candle-power of well-adjusted mantle lamps of the best grade to be as follows: Duration of test, 1000 hours; loss due to mantle alone, 2.5 per cent; loss due to burner alone, 2.5 per cent; loss due to dirt on glassware, 10 per cent; total reduction in candle-power, 15 per cent. Tests of commercial installations receiving skilled maintenance show an average performance from 15 to 25 per cent below the rated candle-power and efficiency. Without skilled maintenance the average performance is generally from 30 to 50 per cent below rated candle-power and efficiency. (*Proc. Nat. Elec. Light Assn., 1911, Vol. I, p. 809.*)

The efficiency of incandescent gas lamps varies with the pressure and the calorific value of the gas. At a given pressure the lumen-hours per cubic foot of gas are closely proportional to the calorific value of the gas. The pressure variations common to most gas systems have little effect on lamp efficiency, as the candle-power and rate of gas consumption are about equally affected.

PERFORMANCE OF GAS ILLUMINANTS. — The curves of Figs. 1 to 3 show the light distribution of the gas illuminants in general use.

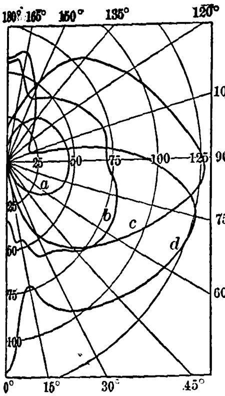

Fig. 1. Light Distribution of Upright, Single-mantle Gas Lamps

a. Junior type, mica chimney, 1.66 cu. ft. per hour
b. Standard type in opal globe, 3.8 cu. ft. per hour
c. Standard type in clear chimney, 4.66 cu. ft. per hour
d. Standard type with opal dome, 4.66 cu. ft. per hour

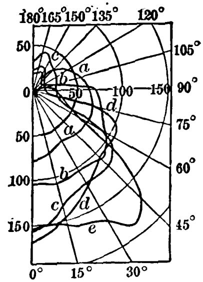

Fig. 3. Light Distribution of Single-mantle Inverted Gas Lamps

a. In roughed glass globe, 3.31 cu. ft. per hour
b. With flat opal reflector, 3.31 cu. ft. per hour
c. With opal dome reflector, 3.31 cu. ft. per hour
d. With enamelled cone reflector, 3.31 cu. ft. per hour
e. With holophane reflector No. 6321, 3.65 cu. ft. per hour
All tests with water gas of 20.5 to 22 c.p.

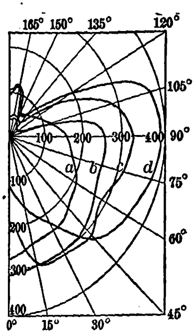

Fig. 2. Light Distribution of Gas Arcs

High-pressure Gas Systems. — The amount of air entrained in the mantle burner at ordinary low pressures is insufficient to produce the highest flame temperature and mantle efficiency. Three methods of gas supply are designed to improve this condition, viz., (*a*) to provide a gas pressure at the lamps of from 40 to 60 inches of water, (*b*) to provide gas at ordinary pressure and compressed air from a separate system of piping and (*c*) to supply both gas and air under pressure. The results produced by the three systems are approximately on a par. Results of the operation in Germany of inverted high-pressure lamps as cited by Wrightington (*Lectures on Illuminating Engineering, Johns Hopkins University, 1911, Vol. 2, p. 872*) may be summarized as follows:

Mantle life, 110 hours. Globe life, 2230 hours. Energy for gas compression, 1 horse-power-hour for 1400 cubic feet of gas. Consumption of 3-burner lamp, 65 cubic feet per hour. Costs per lamp-hour of 3-burner inverted lamp: compression, 0.31¢; maintenance and renewals, 0.58¢; gas at 61¢ per 1000 cubic feet, 3.98¢; total per lamp-hour, 4.87¢; total per lamp-year of 3675 hours burning, $178.97.

The light output of the high-pressure inverted single-mantle lamp is approximately 1500 mean lower hemispherical candle-power for a gas consumption of from 25 to 30 cubic feet per hour. The 3-mantle inverted lamp gives approximately 3500 m.l.h.c.p. at 70 cubic feet per hour. These efficiencies can be sustained only by the most careful attention to maintenance conditions. Fig. 4 shows typical light distribution curves of high-pressure lamps.

Methods of Automatic Ignition. — The automatic ignition of gas lamps may be accomplished by the following methods:

(*a*) A pilot flame consuming from 0.05 to 0.10 cubic foot per hour is fitted to each burner. As the main cock is opened a momentary jet of gas is supplied to the pilot tube, causing the ignition of the main burners. On some remote-controlled street-lighting systems a momentary extra pressure is applied as the gas is turned on to produce this jet action at the local burners.

(*b*) A high-tension spark is produced in the gas issuing at each burner by means of an induction coil. The primary circuit contains a battery, ignition switch and vibrating interrupter. The secondary coil is in series with the several spark terminals and each end of the wire is grounded. Good insulation of the secondary wiring is essential.

(*c*) The mantle may be provided with a small spot of sponge platinum which is raised to incandescence by catalytic action due to the rapid absorption of gas. Such self-lighting mantles are apt to be short-lived.

A clock-controlled ignition cock is frequently employed with show-window lamps and street lamps operated during definite time intervals on a flat rate system of charges.

COST OF GAS LIGHTING. — The following table shows the approximate cost of operation of various gas lamps. The assumed cost of gas is $1.00 per thousand cubic feet and the assumed average light output as 80 per cent of the nominal ratings with clear glassware.

Type of lamp	Cost per 1000 lamp-hours			Cost per 100,000 lumen-hours
	Renewals and maintenance	Gas	Total	
1-Mantle upright	$0.60	$5.00	$ 5.60	$0.65
1-Mantle miniature	0.40	2.00	2.40	0.70
1-Mantle inverted	0.50	3.30	3.80	0.63
4-Mantle upright	1.65	18.80	20.45	0.74
4-Mantle inverted	1.65	13.00	14.65	0.80

Gas vs. Electricity. — For comparison with the above it may be noted that the operating costs of 100-watt tungsten lamps with energy at 5¢ and 10¢ per kw-hr. are respectively $0.75 and $1.40 per 100,000 lumen-hours. Corresponding costs for 250-watt lamps are $0.61 and $1.15 respectively. The advantages of electric lighting are chiefly convenience, flexibility in the size and location of illuminants, non-vitiation of air, small heat output, and freedom from the dangers of explosion and asphyxiation. The chief disadvantages of electric lighting are danger of shock from abnormal voltages, the fire risk of faulty wiring and the greater likelihood of service interruption. The color of high-grade incandescent mantle lamps is a closer approach to daylight than that of the tungsten lamp, but is considered by many as less pleasing.

[W. E. WICKENDEN.]

GAS METERS. — (*See also Gas.*) To determine the volume of gas flowing through a pipe in a given time, either the "dry" or the "wet" type of meter may be used. The "wet" meter, in which a cylindrical drum divided into four equal compartments revolves with its lower half submerged in water, has a limited commercial use because of the liability of the freezing of the water in cold climates and because of the necessary attention required to keep the water level constant. The wet meter, however, forms the most satisfactory standard for testing purposes.

DRY METERS. — The "dry" meter, which is almost universally used, is constructed as shown in Fig. 1. The sheet-iron case is divided into three parts: *A*, *B* and *C*. On the partition separating *A* and *B* are mounted two leather bellows *DD*, the faces of the bellows *EE* consisting of circular plates of sheet iron. In the compartment *C* are placed the gas valves *FF* and the recording dial *G*. The motion of the bellows is communicated to the valves and the gear train of the dial through the arms *HH*, the spindles *II* and the shaft *J*. As the bellows fill and empty, the spindles *II* oscillate and acting together upon the shaft *J* cause it to revolve. The gear train of the dial is then set in motion and the gas valves are opened and closed in synchronism with the motion of the bellows. The inlet and outlet pipes are shown at *K*, the two pipes overlapping in the side elevation shown. The pipe connections between the inlet and outlet pipes *K*, the valves *FF*, and the compartments *DD* and *EE* are omitted from the figure.

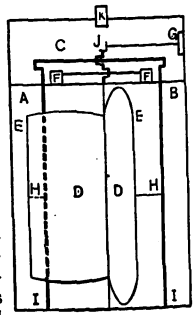

Fig. 1. Dry Meter

Dimensions of Dry Meters. — In the following table are given the standard sizes of "dry" meters, with their capacities and over-all dimensions.

Size, Number of Lights	Capacity, cubic feet per hour	Height, inches	Width, inches	Depth, inches
3	80	15	10	9
5	145	17	12	10
10	210	18	13	11
20	330	22	17	14
30	420	25	19	15
50	510	30	23	20
60	600	32	25	20
80	720	37	27	23
100	900	39	29	25
150	1500	49	35	27
200	2000	55	41	29
250	2500	57	44	30
300	3000	60	46	33
500	5000	73	50	33

[R. G. Hudson.]

GAS PRODUCERS. — (*See also Gas; Gas Engines; Power Stations, Gas-Electric.*) The name gas producer is usually applied to the apparatus used for making and purifying producer-gas (*see Gas*). The name, however, is sometimes limited to the apparatus in which the heating of the fuel takes place, and again it is used to designate the apparatus used in the manufacture of any kind of gas. In this article, the name gas producer will be used as a general term for all the apparatus used in making and purifying producer-gas, including the generator in which the heating of the fuel takes place, the evaporator or boiler for producing the necessary steam, and various filters and scrubbers.

The Generator. — The simplest form of generator is merely a cylindrical structure of fire-brick, provided with a grate, a roof and an outlet for the gas. A bed of coal from three to five feet thick is maintained in it and air and steam are forced through this bed. The oxygen of the air combines with some of the fixed carbon in the coal, forming carbon monoxide, the steam reacts with the heated carbon, forming hydrogen and carbon monoxide, and the hydrocarbons in the coal are driven off by the heat. In addition to adding combustible gases to the gas by its decomposition, the steam diminishes the formation of clinker, reduces the temperature of the escaping gases and makes a gas lower in nitrogen, and, therefore, of higher heating value, than would be produced if air alone were used. For facilitating the removal of ashes, revolving grates are used, or else the grate is dispensed with and the bottom of the producer rests in a shallow pit filled with water, from which the ashes are removed from time to time. The coal is usually fed by filling a hopper set in the roof of the producer, and opening its bottom so as to drop the coal, but sometimes special forms of rotating hoppers or feeders are used which distribute the coal evenly over the bed. To avoid choking of the producer by the "caking" of some varieties of soft coal, stirring apparatus is sometimes used in the upper part of the producer to break up the cake.

Evaporator. — The evaporator is essentially a steam boiler, the water being heated by causing the hot gases from the generator to circulate around the pipes or other container holding the water. The steam thus formed is fed into the generator with the proper proportion of air.

Filters and Scrubbers. — In order to remove the dust, tar and other harmful ingredients, the gas is passed through various devices designed to absorb or precipitate these substances. The filter consists of some porous material, such as shavings, excelsior or sawdust, in a suitable retainer. Liquid "scrubbers" are for the purpose of bringing the gas into intimate contact with water, which absorbs or precipitates the various impurities. This is accomplished by causing the gas to bubble through water, by passing the gas through a chamber into which water is sprayed, or by passing the gas over surfaces continually kept moist by a film of water. The spray type of scrubber is usually a large cylindrical shell filled with coke, the latter aiding in absorbing the tar from the gas as it passes through. Rotating scrubbers are also employed, which may be designed either to mix thoroughly the gas and water, or to drive out the impurities by centrifugal force. Rotating scrubbers are particularly effective in removing tar, a large amount of which is present in gas made from bituminous coal.

TYPES OF PRODUCERS. — The various forms of gas producers, of which there are a great number, differ chiefly in details of construction and in the arrangement of the various parts of the apparatus. There are, however, two distinct types of producers, the "suction" producer and the "pressure" producer. In the former type, the draft through the producer is produced by the suction of the gas engines which are fed from it. This type of producer requires no gas-holder and is very compact. It requires a high-grade fuel, such as coke

or anthracite. An auxiliary starting fan is also necessary, as a draft must be set up through the producer before the engine can be started. The Körting producer is of this type. For large installations, the pressure type of producer is nearly always employed. In this type, air and steam are forced into the producer under pressure, and the gas is collected in a suitable holder. This type of producer can be adapted to the use of practically any kind of fuel. The Mond producer and the Morgan producer are of the pressure type.

UTILIZATION OF BY-PRODUCTS. MOND PROCESS.—Ammonia is about the only by-product of producer gas which has enough commercial value to justify the additional expense required to save it. This saving is accomplished by the Mond process, which is the only one used to any extent in this country, as follows: An excess of steam is injected with the air, lowering the temperature and thereby preventing the destruction of the ammonia in the coal. (The proportion of hydrogen and carbon dioxide in the gas is also increased and the proportion of nitrogen decreased.) The gas, after passing through a mechanical scrubber, is caused to pass through a tower where it is thoroughly washed with dilute sulphuric acid. The ammonia in the gas combines with the sulphuric acid, forming ammonium sulphate. This acid solution of ammonium sulphate circulates through the tower over and over again until it reaches a given degree of saturation; then a certain amount of it is bypassed out of the system and fresh acid is added. In this system, the heat energy lost by the gas in cooling is also used to preheat the air which is used in generating the gas, effecting a considerable increase in the economy of the process.

RATING AND PERFORMANCE. — A gas producer is usually rated in horse-power, the rating being the number of horse-power which can be developed by gas engines supplied from the producer when the latter is gasifying coal at a maximum rate. Such a rating is, of course, indefinite, as the power developed by the engines depends upon their design and the percentage of load which they are carrying, and the rate of gasification depends upon the quality of coal and the care taken in firing. The following data are the results of a series of tests on bituminous coal and lignites made by the U. S. Geological Survey at St. Louis on a 250-horse-power Taylor producer and a three-cylinder vertical Westinghouse 235-horse-power gas engine. These tests are summarized in a paper by R. H. Fernald in the *Jour. West. Soc. Eng., 1907, Vol. 12, p. 551*. The following table is derived from the curves there given.

DATA ON 250 H.-P. GAS PRODUCER

B.t.u. per lb. of fuel as fired	9000	10,000	11,000	12,000	13,000	14,000	15,000
Lb. of fuel per brake hp.-hr	1.9	1.7	1.5	1.3	1.1	1.0	0.95
Lb. fuel per hr. per sq. ft. of fuel bed	11.6	10.2	8.9	7.8	7.0	6.2	5.5
Cu. ft. of gas per lb. of fuel as fired	38	45	52	57	65	74	87
Lb. steam per lb. of fuel as fired	0.30	0.35	0.40	0.45	0.50	0.55	0.60
Efficiency — Per cent of B.t.u. in fuel in gas produced	66	69	70	72	75	80	85

All items in this table affected by load factor are given only for loads ranging from 90 to 100 per cent of full load (235 brake horse-power). The weight of coal per horse-power-hour does not include the coal required to produce the steam injected into the fuel bed. The efficiency is based on calorimetric measurements, no deduction being made for the latent heat of condensation of the water vapor in the products of combustion of the gas.

Dimensions. — F. C. Tryon (*Power, Dec. 1, 1908*) gives the following rules for determining roughly the dimensions of the various parts of a producer plant:

1. Fuel-bed cross-section 0.125 square foot per horse-power capacity. This gives the formula

$$d = \frac{\sqrt{P}}{2.5},$$

where d is the diameter of fuel bed in feet and P the horse-power capacity.

2. For sizes smaller than 100 horse-power, the walls of the generator should be 9 inches thick; for larger sizes, 12 inches thick. Hence, for sizes smaller than 100 horse-power, the external diameter of the generator in feet is $d_0 = d + 1.5$ and for larger sizes $d_0 = d + 2$.

3. Height of generator approximately twice its internal diameter; for sizes under 100 horse-power the height is usually greater than twice the internal diameter while for larger sizes the height is usually slightly less than twice.

4. Diameter of wet scrubber three-fourths of the internal diameter of generator.

5. Height of wet scrubber one and one-half times the height of generator.

6. Diameter of dry scrubbers, of which there should be two, equal to internal diameter of generator.

7. Height of each scrubber 3 to 4 feet for plants ranging from 25 to 200 horse-power.

COSTS. — The following approximate formulas for costs of producer-plant equipments have been derived by Prof. W. E. Wickenden from a large number of actual installations. They include the purchase price of generators, evaporators and the necessary scrubbers and filters, and the cost of erection, but do not include buildings and foundations; P is the horse-power rating of the producer.

Suction producers	$650 + $11 × *P*.
Pressure producers up to 200 horse-power	$1000 + $16 × *P*.
Pressure producers over 200 horse-power	$2000 + $15 × *P*.
Gas holders	$1000 + $0.26 × *P*.

Detailed manufacturers' estimates of investment cost and cost of operation of twenty-six producer plants are given in the paper by Mr. Fernald in the *Jour. Soc. Wes. Eng., 1907, Vol. 12, p. 551.*

[Wm. Kent.]

GEARS AND GEARING. — The following terms are commonly employed.

Gear Wheel or Gear. — A wheel with teeth cut in its periphery, designed to mesh with the teeth of a similar wheel or with a screw or worm.

Pitch Circle or Pitch Line and Pitch Diameter. — Referring to Fig. 1, the two tangent circles *A* and *B* with their centers on the axes of the two gears, are called the pitch circles or pitch lines of the two gears. The diameter of the pitch circle is called the pitch diameter.

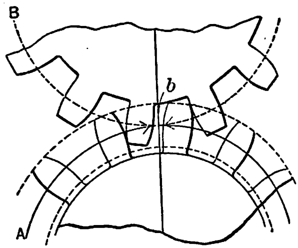

Fig. 1. Spur Gear

Backlash. — Referring to Fig. 1, the distance *b*, which is the difference in the width of the tooth space and the width of the tooth, measured along the circumference of the pitch circle, is called the backlash.

Pitch of a Gear. — The *circular pitch* of a gear is the distance in inches, measured along the *arc* of the pitch circle, between the center lines of two successive teeth; it is also

$$\text{Circular pitch} = \frac{\pi \times (\text{diameter})}{\text{Number of teeth}}.$$

The *chordal pitch* is the distance in inches, measured along the *chord* of the pitch circle between the center lines of two successive teeth; let N be the number of teeth, D the diameter of pitch circle, then

$$\text{Chordal pitch} = D \sin\left(\frac{180°}{N}\right).$$

The *diametrical pitch* is the quotient of the number of teeth by the diameter of the pitch circle.

Pinion. — The smaller wheel of a gearing consisting of two gear wheels is called the pinion; e.g., the gear wheel on the shaft of a railway motor is called the pinion. The name pinion is also used for the smaller of two gears mounted on the same shaft.

Sprocket. — A gear wheel driven by a chain.

Gear Ratio or Velocity Ratio. — The ratio of the number of teeth in the larger wheel of a gearing to the number of teeth in the smaller wheel; this is also equal to "velocity ratio," or the number of revolutions of the smaller wheel corresponding to one revolution of the larger wheel.

Spur Gear. — A gear wheel in which the external surfaces of the teeth lie on a cylinder and the center planes of the teeth pass through the axis of the gear — the common type of gear wheel.

Bevel Gears. — A gear wheel in which the external surfaces of the teeth lie on a cone, so that the gear may mesh with another gear having its axis inclined to the axis of the first.

Stepped Gears. — Two gears of the same pitch and diameter mounted side by side on the same shaft will act as a single gear. If one gear is keyed on the shaft so that the teeth of the two wheels are not in line, but the teeth of one wheel slightly in advance of the other, the two gears form a stepped gear. If mated with a similar stepped gear on a parallel shaft the number of teeth in

contact will be twice as great as in an ordinary gear, which will increase the strength of the gear and its smoothness of action.

Twisted Teeth. — If a great number of very thin gears were placed together, one slightly in advance of the other, they would still act as a stepped gear. Continuing the subdivision until the thickness of each separate gear is infinitesimal, the faces of the teeth instead of being in steps take the form of a spiral or twisted surface, and we have a twisted gear. The twist may take any shape, and if it is in one direction for half the width of the gear and in the opposite direction for the other half, we have what is known as the herring-bone or double helical tooth. This form of tooth is much used in heavy rolling-mill practice, where great strength and resistance to shocks are necessary. They are frequently made of steel castings. The angle of the tooth with a line parallel to the axis of the gear is usually 30 degrees.

Spiral or Helical Gears. — If a twisted gear has a uniform twist it becomes what is commonly called a spiral gear (properly a helical gear). The line in which the pitch surface intersects the face of the tooth is part of a helix drawn on the pitch surface.

Pitch Angle. — The pitch angle of a helical gear is the angle between the center line of the tooth and a line perpendicular to the axis of the gear.

Screw or Worm. — A spiral wheel may be made with only one helical tooth wrapped around the cylinder several times, in which it becomes a screw or worm. If it has two or three teeth so wrapped, it is a double- or triple-threaded screw or worm.

Worm-Gearing. — When the axes of two spiral gears are at right angles and a wheel of one, two or three threads works with a larger wheel of many threads, it becomes a worm gear, or endless screw, the smaller wheel or driver being called the worm, and the larger, or driven wheel, the worm wheel. With this arrangement a high velocity ratio may be obtained with a single pair of wheels. For a one-threaded wheel the velocity ratio is equal to the number of teeth in the worm wheel. The worm and wheel are commonly so constructed that the worm will drive the wheel, but the wheel will not drive the worm.

Differential Gearing. — Various forms of differential gears are used. The object is to devise a motion such that the velocity ratio is equal to the ratio of the number of teeth in one gear wheel to the *difference* between the number of teeth in this gear wheel and the number of teeth in the other wheel. In one form of differential gearing one wheel meshes with a set of teeth on the inside of a second wheel. The second wheel is so arranged that it cannot turn about its own axis but its center is caused to move in a circle concentric with the first wheel.

But for the limitation that the difference between the wheels must not be too small, the possible ratio of speed might be increased almost indefinitely, and one pair of differential gears made to do the service of a whole train of wheels. If the problem is properly worked out with bevel gears this limitation may be completely set aside, and external and internal bevel gears, differing by but a single tooth if need be, made to mesh perfectly with each other.

DESIGN OF GEARS. — In order that the teeth of wheels and pinions may run together smoothly and with a constant relative velocity, it is necessary that their working faces shall be formed of certain curves called odontoids. The essential property of these curves is that when two teeth are in contact the common normal to the tooth curves at their point of contact must pass through the pitch point, or point of contact of the two pitch circles. Two such curves are in common use — the cycloid and the involute.

The design of gears is treated in detail in Kent's *Mechanical Engineers' Pocket-Book* and in Halsey's *Handbook for Machine Designers.*

Materials and Construction.* — Gears are usually made of cast iron or steel. To obtain the most satisfactory results the teeth should be machined. Rawhide pinions, cambric-cloth pinions, and composite gears, consisting of alternate sheets of rawhide or fiber and steel or bronze, are also used where smooth and quiet running are necessary. Of this latter form of gearing the cloth pinions have the advantages of being strong, not liable to damage from cold or hot oil, unaffected by atmospheric changes, and vermin proof.

POWER TRANSMITTED BY GEARING. — The strength of gear-teeth and the horse-power that may be transmitted by them depend upon so many variable and uncertain factors that the formulas and rules given by different writers show a wide variation. The pitches indicated in the accompanying table* are recommended as representing safely conservative practice and, although somewhat smaller teeth may afford sufficient strength in some cases, these standards should be adhered to with as few exceptions as possible.

Maximum horse-power transmitted	Diametrical pitch	Maximum horse-power transmitted	Diametrical pitch
1/6	12	10	4
1/4	10	15	3
1/2	10	20	3
3/4	10	25	3
1	8	50	2½
2	8	60	2½
3	6	75	2
5	6	100	2
7½	5	125	1½
		150	1½

EFFICIENCY OF GEARING. — An extensive series of experiments on the efficiency of gearing, chiefly worm and spiral gearing, is described by Wilfred Lewis in *Trans. A.S.M.E.*, Vol. 7, p. 273. The average results are shown in a diagram, from which the approximate average figures in the table on the following page are taken.

The experiments showed the advantage of spur gearing over all other kinds in both durability and efficiency. The variation from the mean results rarely exceeded 5 per cent in either direction, so long as no cutting occurred, but the variation became much greater and very irregular as soon as cutting began. The loss of power varies with the speed, the pressure, the temperature and the condition of the surfaces.

The excessive friction of worm and spiral gearing is largely due to the end thrust on the collars of the shaft. This may be considerably reduced by roller bearings for the collars. When two worms with opposite spirals run in two spiral worm gears that also work with each other, and the pressure on one gear is opposite that on the other, there is no thrust on the shaft. A low efficiency

* By D. B. Rushmore.

for a worm gear means more than the loss of power, since the power which is lost reappears as heat and may cause the rapid destruction of the worm.

PER CENT EFFICIENCY OF SPUR, SPIRAL AND WORM GEARING

Gearing	Pitch angle, degrees	Velocity at pitch line in feet per min.				
		3	10	40	100	200
Spur pinion	..	90	93.5	97	98	98.5
Spiral pinion	45	81	87	93	95.5	96.5
Spiral pinion	30	75	81.5	89	93	94.5
Spiral pinion	20	67	75	84.5	90	92
Spiral pinion	15	61	70	80.5	87	90
Spiral pinion or worm	10	51	61.5	74	82	86
Spiral pinion or worm	7	43	53	72	76.5	81.5
Spiral pinion or worm	5	34	43	60	70	76.5

[WM. KENT.]

GENERATORS, ALTERNATING-CURRENT. — (*See also Alternating Currents; Electricity and Magnetism, Principles of; Generators, Direct Current-Motors; Standardization Rules.*) The following is a brief table of contents of this article:

In all dynamo-electric machines of the usual forms (excepting the homopolar) the electromotive force induced in any one conductor or turn varies in value and alternates in direction. If the terminals of any coil or group of coils are brought out to an external circuit by means of revolving contacts, such as slip rings, an alternating current will flow in the circuit. In order to obtain a direct or continuous current it is necessary to add a commutator or rectifier. Thus the most simple and elementary form of electric generator is an alternating-current generator and the direct-current generator is a special form adapted by the addition of a commutator to give a continuous or unidirectional current.

CLASSIFICATION. — Alternating-current generators may be classified according to several different distinguishing characteristics. The following classification considers these characteristics in the order of their prominence.

Synchronous Generators. — In the synchronous type the action of inducing the electromotive force results from the relative motion of the armature conductors and a constant magnetic field produced by exciting coils in which a continuous or direct current flows. The frequency of the alternating electromotive force depends directly on the number of field poles and the angular velocity of the revolving part.

Induction Generators. — In the induction type the magnetic field is of the rotating polyphase type and is produced by polyphase alternating currents flowing in the same windings with the load current. The mechanical construction is usually that of an induction motor with a short-circuited polyphase winding on the revolving member. The frequency depends upon the characteristics of the external circuit. In practice the frequency is determined or "set" by a synchronous machine, either generator or motor, in the external circuit. This "frequency setter" is necessary to supply the exciting current of the induction generator; that is, by means of the frequency setter the power factor of the total load is adjusted to equal the inherent power factor of the generator.

Advantages and Disadvantages of Induction Type. — A minority of the units of a station may be of the induction type with advantage as they will cause less disastrous effects in case of a short circuit on the system. Their instantaneous short-circuit current is less. A certain number of the units must be of the synchronous type to "set" the frequency and supply the exciting current for the induction machines. Consequently, if there is a large proportion of induction machines the synchronous machines operate at a poor power factor unless there is much capacity effect in the load system, such as synchronous motors or line capacity.

Revolving-field and Revolving-armature Types. — In the revolving-field or revolving-armature type there are two, or some multiple of two, poles, each pole having its own coil for the direct-current excitation, and the flux in each pole is to all intents and purposes constant in value. The relative movement of the poles and conductors causes the variation in flux interlinkages both in direction and intensity.

The early machines were constructed with an armature revolving inside a stationary field. As sizes and voltages increased it was found that a more effective use of the material could be obtained by making the armature the external member, and that the insulation of the high-voltage member was better preserved if that member was kept stationary.

At the present time all generators of large capacity (500 kilowatts and greater) and for high voltages (600 volts and up) are made of the revolving-field type.

Inductor Type. — In the inductor type the direct-current excitation is concentrated in one (usually stationary) coil and the variation in magnetic flux is obtained by revolving a spider with bare projecting poles which alters the reluctance of the magnetic path. Thus the flux threading any particular armature coil is always in the same direction, but varies in intensity or quantity.

Comparison of the Inductor Type with Revolving Field or Revolving-armature Type. — There are no windings or insulation on the moving member of the inductor type, which is, therefore, adapted to high speeds. The shorter and more compact magnetic circuit of the revolving-field or revolving-armature type, however, makes for a better voltage regulation. This type is also better adapted to operation in parallel with other generators. It is the type in by far the most general use.

Single Phase, Two Phase or Quarter Phase and Three Phase. — The single-phase generator is usually about 30 per cent heavier and more costly than a polyphase generator of the same rating. By changing the internal armature connections a polyphase machine may frequently be reconnected to be a three-, two- or single-phase machine.

As transmission by three-phase currents is more economical of copper than by two-phase or single-phase currents, all power transmission lines are three phase. Consequently unless there is some local condition requiring single or two phase, the three-phase generator is preferable.

Two-phase and three-phase generators of the same capacity and voltage strain are of practically the same dimensions, weight and cost.

Trade Terms. — It has become almost universally the custom to classify an alternating-current generator as *ASB*, *AQB* and *ATB*; the *A* standing for alternator, *S* for single phase, *Q* for quarter phase, *T* for three phase and *B* for revolving field.

Separately-excited and Self-excited Types. —For years it was attempted to develop a satisfactory and simple self-excited alternator and some were very successful but not simple. The object was to obtain a constant voltage on the load by means of automatic self-excitation. However, with the perfection of the automatic voltage regulator the need for automatic self-regulation ceased, and there is now very little demand for self-excited alternators.

METHODS OF RATING. — While generators have been built to meet many different special specifications, it has generally been found more economical to adopt one of the three ratings standardized by the large manufacturing companies. These rating specifications are summarized below. However, it should be noted that **in the standardization rules issued by the A.I.E.E. in 1914 a number of radical changes in methods of rating are recommended;** see article on *Standardization Rules of the A.I.E.E.*

A-Rating. — Generator designed to give the rated load in kilowatts at 100 per cent power factor continuously with a maximum rise in temperature by thermometer of 45° C. above the surrounding air at 25° C. Allowances for other temperatures of the air to be made in accordance with instructions given in the *Standardization Rules of the A.I.E.E.*, Edition of 1911. Also required to give for 2 hours an output in kilowatts, at 100 per cent power factor, 25 per cent greater than the rating, with a maximum rise in temperature by thermometer of 55° C. above surrounding air at 25° C., the overload condition occurring immediately after the machine has been running for some hours at the rated load.

The A-rating has been most generally used, particularly for lighting and general power-station installations.

B-Rating. — Generator designed to give the rated output in kilowatts at 100 per cent power factor continuously with a rise in temperature by thermometer not to exceed 35° C. above the surrounding air at 25° C., and to give 50 per cent more than rated load in kilowatts for 2 hours with a rise in temperature by thermometer not to exceed 55° C. above the surrounding air at 25° C., the overload occurring immediately after a run for a stated number of hours at rated load.

The B-rating was designed particularly for railway work and is desirable in cases of varying loads, loads varying from moment to moment as well as loads with pronounced peaks for an hour or two.

Continuous or "Maximum" Rating. — Generator designed to give continuously the rated load in kilowatts at 100 per cent power factor with a maximum rise in temperature of any part of 50° C. above the surrounding air at 25° C. (or above the incoming air at 25° C. when forced ventilation is used) corrected as per 1911 edition of the *A.I.E.E. Standardization Rules*. This type is not designed to give any overloads except momentarily.

The maximum rating has been developed particularly to harmonize the characteristics of the electric generator with the steam turbine. The rating of the generator corresponds to the maximum economical rating of the turbine. If the generator is driven by a water wheel the maximum rating corresponds to the maximum continuous rating of the wheel at full gate opening.

VOLTAGE. — Alternators are now built to generate voltages up to 13,000 and 15,000 volts between lines, either single phase or polyphase. Above that voltage the extra cost of the insulation and the danger of damage from discharges cause it to be less expensive to install transformers with a lower voltage alternator. Some engineers consider the limit of economical voltage of generators to be even lower than 13,000 volts.

FREQUENCY. — The frequency depends upon the speed of rotation and the number of poles. If the speed of rotation of the revolving part is given in revolutions per minute, the frequency is

$$f = \frac{\text{r.p.m.}}{60} \times \frac{\text{number of poles}}{2}.$$

In the early alternators it was found much more economical to run at high speeds, and thus high frequencies, such as 133 and 125 cycles per second, were customary; but, as systems increased in size and complexity, electrical difficulties arose as a result of these high frequencies and the tendency has been to reduce the frequency till now we have 60, 50, 40 and 25 cycles per second as usual frequencies, of which 25 and 60 are standard in this country. In Europe 50 cycles is used instead of 60. Of late there has been an attempt to have 15 or 16 cycles standardized for railway work.

A frequency of 25 cycles is preferable where there is a very long transmission line, on account of the lower inductive voltage drop, and where there is much synchronous machinery, such as synchronous motors and rotary converters, as these are more stable and better adapted to parallel operation at low frequencies.

A higher frequency (60 cycles in U. S. A., and 50 in Europe) is preferable for electric lighting, as the light is steadier. The higher frequency is also preferable where many transformers are used, as these are cheaper and more efficient at the higher frequencies.

PHASE AND LINE VOLTAGES AND CURRENTS. — For moderate voltages, up to 3000 between lines, the method of connection is decided by such details, as which will give a convenient number for the conductors per slot for the required voltage, but for higher voltages the Y connection is usually chosen as it causes a lesser strain on the machine insulation for a given voltage between lines. See also p. 645.

Single Phase. — In a single-phase generator the voltage per phase is the same as the voltage between lines and the current per phase is the same as the current per line, the product of voltage and current giving the volt-ampere rating of the machine.

Two Phase or Quarter Phase. — In a properly designed machine of this type each phase supplies half the rating, thus the voltage and current per phase in the machine are respectively the same as the voltage and current per phase on the line. The current is equal to $1000 \times$ (kv-a.) $\div 2 \times$ volts per phase.

Three Phase. — Machines of this type may be connected either Y or Δ. In a Y-connected machine the current per phase is the same as the current in each line and is equal to $1000 \times$ (kv-a.) $\div \sqrt{3} \times$ (volts between lines), while the voltage per phase is (volts between lines) $\div \sqrt{3}$.

In a Δ-connected machine the line current is equal to $1000 \times$ (kv-a.) $\div \sqrt{3} \times$ (volts between lines) and the current per phase is equal to (line current) $\div \sqrt{3}$, while the voltage per phase is equal to the voltage between lines.

DESIGN. — The procedure in designing an alternating-current generator for a given power output, voltage and frequency to fulfill given requirements regarding regulation, efficiency, etc., is partly analytical and partly empirical. The data of four specific designs are given below in the section on *Examples of Design and Performance*. The method of procedure is to lay out a preliminary design from rough calculations, calculate the performance of this design, modify the preliminary design where this calculation indicates, recalculate the performance, etc., until a design is arrived at which meets the given requirements.

Definitions. — The following terminology is used in the discussion of the design of generators:

Pole Arc. — The arc subtended by one pole face, measured along the periphery of the armature; in the following discussion it will be expressed in inches.

Pole Pitch. — The arc measured along the periphery of the armature from the center of one field pole (N-pole, say) to the center of the next field pole (S-pole); in the following discussion it will be expressed in inches.

Ampere Conductors per Inch of Armature Periphery. — The product of the number of conductors per inch measured along the periphery of the armature by the effective amperes flowing in each conductor.

Slot Pitch. — The distance in inches measured along the armature periphery between the centers of two adjacent slots. The slot pitch is equal to the pole pitch divided by the number of slots per pole.

Coil Pitch. — The number of slots spanned by a coil; that is, if a coil has one side in slot number 1, and the other side in slot number 7, the pitch of the coil is $7 - 1 = 6$. A coil which spans a distance exactly equal to the pole pitch is said to have a "full pitch," but if it spans a lesser distance it is said to have a "fractional pitch." For example, if there are six slots per pole and a coil has one side in slot number 1, and the other side in slot number 5, it is said to have a fractional pitch of $\frac{4}{6}$ or $\frac{2}{3}$.

Leakage Factor. —The ratio of the flux per pole which enters the armature core to the total flux (including the leakage flux) which would be produced by the field winding.

Preliminary Calculation of Main Dimensions. — Let

P_0 = output in kilovolt amperes (kv-a),
ρ = ratio; pole arc divided by pole pitch,
B = average magnetic flux density per square inch in air gap,
σ = ampere-conductors per inch of periphery,
V = peripheral velocity in feet per minute at gap,
D = diameter of armature in inches,
L = length of armature along shaft in inches,
N = revolutions per minute,
p = number of poles,
f = frequency in cycles per second,
$A = D \div p$.

Then the following relation holds for either a single-phase or a polyphase machine:

$$P_0 = \frac{\rho B \sigma V D L}{144 \times 10^9}. \quad * \qquad (1)$$

Five of the six design constants in the right-hand member of this equation are subject to choice; the equation then fixes the sixth constant. The choice of the values of the various constants should be based upon modern practice, an idea of which is given below.

Ratio of Pole Arc to Pole Pitch (ρ) is governed by two antagonistic phenomena; for the sake of small magnetic leakage and good form factor of e.m.f. wave a low value is desired; for the sake of low reluctance to the main flux and economy of material a high value is desired. The usual values are ranged from 0.6 to 0.7.

Magnetic Flux Density (B) is limited by the exciting ampere turns required to produce it, length of gap and sometimes by the heating resulting from core loss. Usual values B are given in the accompanying table.

Cycles	Lines per sq. in.
25	44,000 to 58,000
60	32,000 to 48,000
125	30,000 to 40,000

Ampere-Conductors per Inch of Periphery (σ) is limited by the heating resulting from high current densities. If ventilation is good, insulation thin, or if the slots are very deep, as in armatures of large diameters, the values of σ may be high. Usual values of σ for continuous rating and for a rise in temperature of 40° C. are:

* For an exact check the constants of p. 629 must be introduced.

Diameter of armature, in.	Less than 500 volts	500 to 2000 volts	2000 to 7000 volts	Above 7000
0 to 20	250 to 350	200	...	...
20 to 30	350 to 600	400	300	250
30 up	600 to 900	700	500	400

Naturally, with special means of ventilation, σ may be much greater than the values here given, as, for example, in turbo-alternators with forced ventilation.

Peripheral Velocity (V) is altogether a matter of mechanical design and values may be found from 2000 feet per minute to 10,000. Usual values are from 3000 to 6000.

Diameter and Length of Armature. — The diameter of armature (D) is related to the number of revolutions per minute (N) by the formula

$$D = \frac{12\,V}{\pi N}.$$

Hence, for a given value of N, the diameter D is fixed when V is chosen. This value of D together with the chosen values of ρ, B, σ and V then fixes the value of L by equation (1).

If, however, the value of N is not given, reasonable values for D and L may be found by assuming that, in accordance with normal and economical conditions, L is approximately equal to the pole pitch. This gives, putting A = diameter divided by number of poles, $L = \pi A$, and equation (1) reduces to

$$P_0 = \frac{\pi\rho B\sigma VAD}{144 \times 10^9}.$$

This fixes D when ρ, B, σ, V and A are chosen. The value of D must, of course, be adjusted to the frequency and an even number of poles (*see next paragraph*). Usual values of the diameter per pole are given in the accompanying table.

Cycles	A = diameter per pole, in.
25	5 to 6
60	2.5 to 3
125	1.75

Number of Poles (p) **and Revolutions per Minute** (N). — The number of field poles is related to revolutions per minute N and the frequency f by the formula

$$f = \frac{Np}{120}, \quad \text{or} \quad p = \frac{120f}{N}.$$

Hence when the frequency and speed are both given, the number of poles is fixed. When N is not given, but L is assumed approximately equal to πA as above, the number of poles is found, when D has been determined, from the relation

$$p = \frac{D}{A}.$$

A value of A must of course be chosen such that p is an even number. The speed N is then obtained from the relation

$$N = \frac{120f}{p}.$$

Armature Windings. — While there are many forms of armature windings which may be used, there are practically only two forms that are in general use in this country. These are the "Chain Winding" and the "Lap Winding."

Chain Winding (Fig. 1). — This winding is characterized by having a number of coils equal to half the number of slots; that is, there is only one side of a coil in each slot. The coils may be either form wound and insulated, in which case slots with open faces are required; or they may be wound by hand in place, in which case partly or entirely closed slots may be used.

There are at least two kinds of coils in each machine. These are characterized by the shape of their end connections, as these end connections lie some in one plane and some in another. If there is more than one slot per pole per phase, there must be four different shapes of coils, having two different pitches; the coils of any one phase per pole are placed concentrically. The chain winding is most generally used in high-voltage machines, 2000 volts or higher.

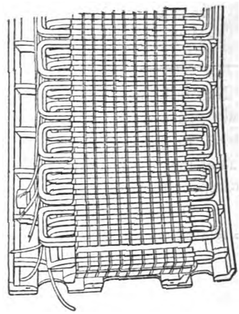

Fig. 1. Chain Winding

Lap Winding (Fig. 2). — This winding contains a much larger number of coils, all of the same form and size. There may be two, four, six, etc., sides of coils in each slot, the coils being placed side by side two coils deep. This winding is similar to the multiple-drum winding of a direct-current armature. With two coil sides per slot the slots must be open, but with more than two coil sides per slot the slots may be partly closed. This type of winding is satisfactory for low voltages and very convenient if there are a large number of slots per pole.

The coils are connected in groups of 2, 3, etc., per pole per phase, depending upon the slots per pole per phase. Successive groups or poles of the same phase are connected in series or multiple by "pole connections."

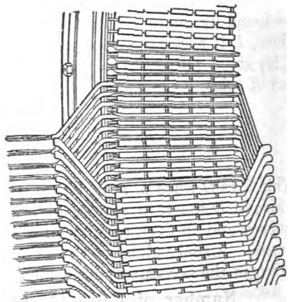

Fig. 2. Lap Winding

In both forms of winding each coil may contain from one to many turns in series.

Turns in Series per Phase (S). — Let

σ = ampere-conductors per inch of periphery,
D = diameter of armature at gap,
Q = number of phases,
I = effective amperes per phase at rated load,
S = turns in series per phase.

Then, for a uniformly distributed winding, such as is used in two- or three-phase machines, and all conductors of each phase in series,

$$S = \frac{\pi \sigma D}{2\,QI}.$$

If the conductors are arranged in 2, 3, or more parallel paths, the factor 2 in the denominator should be changed to 4, 6, etc., respectively. For single-phase machines *see special treatment* below.

Number of Slots. Pitch of Slots (s). — The number of slots per pole in the armature of a two-phase generator may be any multiple of 2, and in a three-phase generator any multiple of 3. The pitch of the slots for any assumed number of slots per pole is

$$s = \frac{\pi D}{p \times (\text{slots per pole})},$$

where D is the diameter of the armature at the gap and p the number of poles.

Number of Conductors per Slot is $\sigma s/I$, where σ is the number of ampere-conductors per inch of periphery, s the slot pitch, and I the effective full-load amperes per phase.

Size of Conductors. — The size of each conductor is a compromise between a size which will give a reasonable current density in the conductor, and a size which will properly fill a reasonable slot (*see discussion of magnetic circuit below*). The current density in the copper conductor should be from 2500 amperes per square inch in small machines to 2000 in medium and moderate voltage and 1600 in high-voltage machines.

The conductors are arranged in the slots so that the slots are usually about four times as deep as they are wide. The size of the slots should be such as to allow a space for insulation over and above the space occupied by the conductors and such cotton covering as they may have. The space required for this extra insulation in straight slots is as follows:

Voltage	Coil sides per slot	Insulation, inches	
		Vertical	Horizontal
500	2	0.350	0.150
2,000	2	0.430	0.160
3,000	2	0.50	0.30
5,000	1	0.75	0.375
6,600	1	0.835	0.50
13,000	1	1.125	0.75

For example, the necessary vertical depth of slot may be found in a machine insulated for 2000 volts with 2 coil sides per slot by multiplying the over-all diameter of cotton-covered wire, or depth of bar, by the number of conductors in a vertical row and adding 0.43 to the product.

Slot Factor. — The ratio of cross section of copper in a slot to cross section of slot is known as the slot factor. Normal values of the slot factor for a 1000-kilowatt machine are given in the accompanying table. For smaller machines the slot factor is slightly less and for larger machines slightly greater.

Voltage	Slot factor
500	0.5
1,000	0.46
2,000	0.42
4,000	0.35
6,000	0.33
10,000	0.30

Preliminary Dimensions of Magnetic Circuit. — The diameter of the armature and the axial length of the pole face for the preliminary design are fixed by the above calculations. There remain to be determined the air gap, the

dimensions of the armature teeth, the length and radial depth of the armature iron, the dimensions of the field poles, and the dimensions of the field yoke. Preliminary values for these quantities may be arrived at as indicated below.

Air Gap. — The minimum clearance between armature core and field poles in modern generators is given in the accompanying table. The average length of the air gap, due to the chamfer on the poles, is about 25 per cent greater.

Armature Diameter, in.	Minimum air gap, in.
40	0.125
80	0.160
120	0.200
160	0.312
200	0.440
240	0.500

Armature Teeth. — The dimensions of the armature teeth depend upon the number and dimensions of the slots, which in turn must be such as to contain the necessary conductors. Another important limitation to the width of the teeth, however, is the value of the magnetic flux density therein. Let s = pitch of slots, a = pole arc, g = average radial depth of air gap. Then the effective number of teeth under each pole is $(a + 2g) \div s$. The effective width of the tooth is its width at a section one-third the distance from its minimum width towards its maximum width. The effective axial length of the teeth is approximately equal to 0.9 of the axial length of the pole face L determined above. From these data the effective cross section of the teeth perpendicular to the flux lines is determined, and this divided into the total flux per pole ϕ gives the average flux density in the teeth. The value of ϕ from the preliminary calculations above is $\pi \rho LDB \div p$, where ρ = ratio of pole arc to pole pitch, D = diameter of armature at gap, B = average magnetic flux density in gap, and p = number of poles. The average flux density in the teeth in modern alternating-current generators ranges from 90,000 to 110,000 lines per square inch.

Armature Core. — The axial length of the armature core is usually slightly greater than the axial length of the pole face. A fair allowance is twice the radial depth of the air gap. The core is usually built up of sheet-steel punchings, 14 mils thick, the punchings having received previously a thin coat of varnish. Ventilating ducts from ⅜ to ½ inch in width (measured along the shaft) are usually provided, these ducts dividing the core into sections from 2.5 to 3 inches thick (measured along the shaft). The effective axial length of the armature iron is therefore the total length of the armature core less the space occupied by the air ducts and insulation between punchings. This latter is about 10 per cent of the net length after deducting the space occupied by the air ducts.

One-half the total flux per pole passes through each section of the armature core. The flux density in the armature core of modern alternating-current generators ranges from 50,000 to 70,000 lines per square inch. Let B_a = the value of the flux density chosen, l = effective axial length of armature iron, ϕ = flux per pole. Then the necessary radial depth of the armature core is $\phi \div 2 B_a l$.

Field Poles. — The axial length of the pole face f is about 0.5 in. less than L, the length of armature. The pole arc a has already been determined. The radial length of the magnet core (c in Fig. 3, see below) and the width of the magnet core (b in Fig. 3) have yet to be determined. The width of the magnet core is usually from 65 to 75 per cent of the pole arc (see Fig. 3), and the radial length in modern machines from 50 to 150 per cent of the width. The dimensions chosen must be such that the core will accommodate the field spool, the approximate size of which is determined as follows:

The number of ampere turns required per pole to force the flux through the

air gap is: $0.313\ \phi g \div af$, where ϕ = flux per pole; g = average radial depth of gap; a = pole arc, and f = axial length of pole face. The ampere turns required for the rest of the magnetic circuit is about 40 per cent of this for most 25-cycle machines and 20 per cent of this for most 60-cycle machines. Hence the total net ampere turns required to produce the flux ϕ is approximately $0.44\ \phi g \div af$ for 25-cycle machines, and $0.38\ \phi g \div af$ for 60-cycle machines. The actual ampere turns required on each field spool at full load, however, will be greater than this, on account of the armature reaction, by an amount depending upon the armature ampere turns per pole and the power factor. For preliminary calculations of the field winding space, however, it is sufficient to increase the net ampere turns as above calculated by about 50 per cent, giving as the approximate total number of ampere turns per pole $F = 0.66\ \phi g/aL$ for 25 cycles and $F = 0.57\ \phi g \div aL$ for 60 cycles.

It is usual to allow a current density of 1000 amperes per square inch in the field copper. The cross section of the copper in the winding is then $F \div 1000$. The total cross section of the winding including the cotton insulation and interstices will be 40 per cent greater than the cross section of the copper when wire is used, and 15 per cent greater when strip is employed. The field pole may then be laid out to accommodate this winding, which is usually wound on a spool, allowing ⅜ inch for the insulating collar at each end, and 0.25 inch for the thickness of the spool and protecting material.

In deciding upon the width of the core, the flux density in the core should also be considered. This should not exceed 100,000 lines per square inch in a laminated steel core. Let ϕ = useful flux per pole, ν = leakage factor, f = axial length of core, b = width of core, then the flux density is $B_c = \nu\phi \div bf$. The value of ν in modern generators ranges from 1.1 to 1.5.

Field Yoke. — The diameter of the armature and the radial length of air gap and field magnet cores fixes the internal diameter of the field yoke (or external diameter in case of revolving-armature type). The radial depth of the yoke, which is usually of cast iron or cast steel, is determined by the flux density desired. Let ϕ = useful flux per pole, ν = leakage factor, e = axial length of yoke, and B_y the flux density in the yoke, then the radial depth is $\nu\phi \div 2\ B_y e$. In modern machines B_y ranges from 25,000 to 30,000 lines per square inch in cast-iron yokes, and from 70,000 to 80,000 lines per square inch in cast-steel yokes.

Field Winding. — It is unnecessary to attempt an accurate calculation of the field winding until a design of the armature and magnetic circuit has been adopted which will give the required regulation. The method of calculating the regulation and determining the number of field ampere turns is given in the next section.

After the excitation in ampere turns per pole required for various loads and power factors desired (according to the specifications or the service required of the generator) has been determined, that condition of operation which requires the greatest number of ampere-turns F is selected. A field winding which will give this excitation and a margin for safety, with the exciter voltage specified, is then designed. Using this value of F and a current density of 1000 amperes per square inch, the cross section of the field winding is $1.4\ F \div 1000$ when made of insulated wire, or $1.15\ F \div 1000$ when made of insulated strip. The length of the coil will be $c - 0.75$ (see Fig. 3), allowing ⅜ inch at each end for the collar and insulation. Therefore the depth of winding will be for wire $\delta = 1.4\ F \div 1000\ (c - 0.75)$ + thickness of spool on which the wire is wound, or $\delta = 1.15\ F \div 1000\ (c - 0.75)$ + thickness of spool. The spool is usually 0.25 inch thick.

The radiating surface of the coil is then

$$A = 2\,c\,(f + b + 4\,\delta).$$

Resistance and Temperature Rise of Field Winding. — The rise in temperature per watt radiated per square inch of surface of a field coil depends on the peripheral speed of the revolving field or revolving armature. The accompanying table gives the temperature rise in degrees centigrade per watt radiated per square inch. For other rates of radiation the temperature rise is proportional. Let w = watts radiated per square inch for the assumed temperature rise (usually 45° C.), A = area of radiating surface, then the allowable loss per pole is wA, and the field current is then $I_f = wA \div v$, where v = volts per pole. The volts per pole should be taken as 80 per cent of the exciter voltage divided by the number of poles (all field spools in series), allowing 20 per cent for emergencies (low speed, etc.). The number of field turns per pole is then $t = F \div I_f + 0.5$, the half turn being added for convenience in connecting up. The proper resistance (r) of the field winding is then $wA \div I_f^2$, and the necessary cross section (q) of the conductor in square inches is

	Peripheral speed, ft. per min.	Temp. rise ° C. per watt per sq. in.
Revolving field	1,000	45
	2,500	40
	5,000	25
	10,000	15
Revolving armature	1,000	80
	2,500	60
	5,000	45
	10,000	30

$$q = \frac{0.0186\, t\, (f + b + 2\,\delta)}{12{,}000\, r}.$$

(The resistance of 1000 feet of copper 1 square inch in cross section at 60° C. is 0.0093 ohm and $2\,(f + b + 2\,\delta)$ is the mean length of turn.) From this cross section the nearest size of wire may be chosen and r, w and volts per pole calculated by reversing the above procedure.

The cross section of the winding should now be recalculated, and the necessary adjustments made to make it fit the winding space available on the field poles.

Bearings, Shafts, Bedplates, etc. — Alternating-current generators may be belt-driven or direct-connected and the latter type may have either a horizontal or vertical shaft.

Belt-driven generators are only used in the smaller sizes up to 500 kilowatts. The smallest sizes usually have two bearings and an overhanging pulley. The larger sizes frequently have three bearings and the weight of the pulley and pull of the belt are taken by two of the bearings.

Generators with horizontal shafts for direct connection to water wheels are usually built with two bearings and a coupling and are complete in themselves, i.e., they have bedplates, shafts and bearings.

Generators with horizontal shafts for direct connection to steam engines are usually built without bedplates, shafts or bearings. The generator frame is supported on the foundation by a suitable sole plate. The engine bearing serves for one of the generator bearings. The revolving field is carried by an extension of the engine shaft. The shaft and bearings are usually furnished by the engine builder and the revolving member of the generator is pressed on the shaft at the factory where the generator is built.

Vertical shafts are sometimes used with water-wheel-driven generators, and in this case the weight of the revolving part of the generator may be balanced by the upward thrust of the water jet.

In some machines of the revolving-field type the magnetic yoke is made

extremely large to serve as a flywheel. Such machines are known as flywheel generators.

For the purpose of preparing the foundations for the generator, the manufacturer usually supplies in advance a template showing the shape and size of bedplate, number, size and spacing of bolt holes.

Design of Turbo-Generators. — In turbine-driven generators the steam turbine is usually built by the same company that builds the generator and the two machines are practically one unit. The steam turbine has developed to such an extent that for a given capacity in power it weighs less than a reciprocating engine, occupies much less space, costs less and is fully as economical of steam if not more economical. Good economy in steam turbines, however, is obtained only with high angular velocities. This has made it very difficult to apply the turbine to useful purposes. The electric generator has shown itself to be the most natural device to absorb the power of the turbine and make it available for various applications in a convenient form. However, it required many years of experience to develop an electric generator which would operate successfully at the high angular velocities suitable for direct connection to the steam turbine. The principal difficulty was the design of a construction which would withstand the enormous stresses in the revolving member which resulted from the centrifugal force. Thus the design of the machine as a whole turns upon the type and construction of the rotor, which is usually in the form of a revolving field.

Normal Weights and Speeds. — Most turbo-generators have much more copper on the fields and less on the armature than do slow-speed machines, although the total amount of copper is not far different in the two classes of machines. It is quite normal to build machines of from 1000 to 5000 kw. capacity to operate at 3600 r.p.m. and machines of 10,000 kw. at 1800 r.p.m. To do this involves the use of peripheral speeds of from 15,000 to 25,000 feet per minute. At these high speeds the amount of material per kilowatt is much reduced. Increasing the speed ten fold reduces the weight of material to about one-quarter. Thus these machines have a lesser cost per kilowatt of capacity. But this low weight is somewhat offset by the higher cost of the construction necessary to withstand the enormous centrifugal forces. Most of the machines, even the large sizes, have two or four poles or at most six poles. This necessitates the use of a pole pitch of from 25 to 30 in. in 60-cycle machines and 50 to 60 in. in 25-cycle machines. Since such large powers are concentrated in such small bulk a great deal of energy in the form of losses must be dissipated from a small space. Thus special means of ventilation must be provided such as numerous air ducts, fan blades on the rotor or a separate blower and air ducts. Usually from 15 to 20 per cent of the whole length is occupied by air ducts.

Methods of Rotor Construction. — The centrifugal force in the revolving member is from 1000 to 1500 lb. for every pound of material. A method for determining the centrifugal force in every part is given in *Electric Machine Design* by Gray and *High-speed Dynamo-electric Machinery* by Hobart and Ellis. The rotor must be of substantial and rigid construction so that the critical speed of vibration is above the normal speed of operation. There are several methods of construction, prominent among which are:

a. Steel punchings with radial slots, assembled on a forged steel shaft with the distributed windings held in place by wedges and bronze end rings.

b. A steel forging with a distributed winding in parallel slots milled in the periphery, the shaft either being in one piece with the forging (4 poles) or bolted on at the ends (2 poles).

c. Laminated pole pieces attached to the spider by keys and holding four or more concentrated field coils.

In these revolving fields the diameter is not much greater than the length of core and the air gap is quite large compared to the diameter; for instance, diameter 48 in., length 40 in., gap 1.25 in. A symmetrical air gap is necessary to prevent noise and undue strains. A sine distribution of flux is desirable to reduce magnetic losses and give a good wave form to the electromotive force of the armature. This is obtained by using a distributed field winding of concentric coils. The pole arc is usually from 60 to 65 per cent of the pole pitch, the flux per pole very high, and the average gap density lower than in slow-speed machines, since due to the sine distribution the maximum density in the gap is 1.57 times the average (usual value of maximum density 50,000 lines per square inch).

Construction of Stator. — Since the pole pitch is large, a large number of slots per pole are used (4, 6 and 8 slots per pole per phase) and this gives a low armature self-inductance and high short-circuit current. Due to the long pole pitch the end connections are long and subjected to considerable mechanical forces as a result of the leakage flux. They must, therefore, be well held in place by non-magnetic supports. For armature reaction in ampere turns per pole values from 6000 to 8000 are common and the field winding is usually of a capacity three times the armature ampere turns, namely, 18,000 to 24,000, giving a regulation of from 4 to 6 per cent. The current density in the copper (2000 amperes per square inch) is lower than in slow-speed machines. The constant, "ampere conductors per inch periphery," has values from 500 to 800.

Provision for Ventilation. — The ventilation of these machines is a problem similar to that of air-blast transformers. Thus there must be provided: (*a*) Sufficient air to carry off the heat generated with a reasonable rise in temperature of the machine and the air. (*b*) Ample duct capacity to prevent too high velocity of the air. (*c*) Proper spacing of the ducts so that there is no part very far from an air duct. (*d*) Proper precautions to prevent the air from carrying dirt and moisture into the machine.

Lamme (*Trans. A.I.E.E.*) states that 100 cu. ft. of air per minute will carry off 1 kw. with a rise (of the air) of 18° C. Velocities of the air of from 5000 to 6000 feet per minute are common in the machine proper. The surface cooled will give off 4 or 5 watts per square inch with a rise of 35 to 40° C. above the cooling air.

PREDETERMINATION OF PERFORMANCE OF A GENERATOR FROM ITS DIMENSIONS. — From the above calculations a preliminary drawing to scale of the machine may be laid out. The next step is to calculate its performance, i.e., predetermine what will be the regulation, the efficiency and the temperature rise in the various parts.

The calculations for a quarter-phase or a three-phase machine are very similar and are given together in the paragraphs immediately following. The special features of a single-phase machine are described below. Examples of specific designs and the tested performance are also given below.

Magnetization Curve. — The first step is the calculation of the magnetization curve, i.e., a curve showing the relation between the voltage per phase at no load (at normal speed) and the field ampere turns. To do this the useful flux per pole corresponding to any given value of the no-load voltage is first calculated, and then the field ampere turns per pole required to produce this flux are determined. A sufficient number of points to give a magnetization curve up to 20 per cent above rated voltage should be calculated.

Useful Flux (i.e., the flux cut by the armature conductors). — Let

E = a given value of the terminal voltage per phase with zero armature current,

f = frequency in cycles per second,

S = number of turns in series per phase,
k_1 = a constant, depending on the shape of the pole shoe, which may be called the "pole shoe constant,"
k_2 = a constant, depending on the distribution of the armature winding, which may be called the "winding-distribution constant,"
k_3 = a constant, depending on the pitch of the armature coils, which may be called the "pitch constant."

Then the useful flux per pole entering the armature is

$$\phi = \frac{E \times 10^8}{4.44\, k_1 k_2 k_3 f S}.$$

Pole Shoe Constant (k_1). — This constant is proportional to the form factor of the flux distribution around the periphery of the armature. In all modern machines the pole faces are so shaped that this distribution is practically a sine wave, and therefore $k_1 = 1$. This is usually done by making the air gap at the pole tips greater than at the center of the pole.

One method of doing this is to make the outline of the pole face a portion of a circle of such a radius (less than the radius of the armature in revolving field machines) that the gap at the tips is twice the gap at the center.

For very accurate predeterminations the distribution of the flux is carefully calculated. (*See S. P. Thompson, Dynamo Electric Machinery, Vol. II, p. 206; C. A. Adams, Trans. A.I.E.E., Vol. 33.*)

Winding Distribution Constant (k_2). — This constant allows for the fact that if there is more than one slot per pole per phase, the conductors in the various slots of one phase under a pole do not generate e.m.f.'s of exactly the same phase. Since the slots pass under the pole consecutively the e.m.f.'s of the conductors reach a maximum consecutively. These e.m.f.'s must therefore be combined vectorially and not merely added together. k_2 is different in single-phase, two-phase and three-phase machines.

The following table gives the values of k_2 for uniformly distributed windings with equally spaced slots.

Slots per pole	Value of k_2		
	1 phase	2 phase	3 phase
1	1.000	.....	.....
2	0.707	1.000	.....
3	0.666	.....	1.000
4	0.65	0.925	.....
6	0.64	0.912	0.966
8	0.64	0.905	.....
9	0.64	.....	.....
12	0.64	0.90	0.960
18	0.64	0.90	0.960
24	0.635	0.90	0.958
∞	0.632	0.90	0.958

These constants apply to a winding uniformly distributed around the armature periphery. This is always the condition in a two- or three-phase machine. A single-phase machine usually has its working winding irregularly distributed,

so the above constants are only of theoretical interest. (*See special treatment of single-phase machines below.*)

Pitch Constant (k_3). — It is sometimes desirable to use coils having a fractional pitch, particularly in machines of large pole pitch, in order to save copper and I^2R loss, and also in any machine to give a particularly good wave shape. When this is done each turn connects in series two conductors generating e.m.f.'s which are not in phase and their resultant is therefore not as great as their arithmetic sum. The constant k_3 is the ratio of this resultant or vector sum to the arithmetic sum of the two e.m.f.'s. The relation between k_3 and winding pitch expressed as a percentage of the pole pitch is given in the accompanying table.

Per cent pitch	k_3
100	1.00
83	0.97
80	0.95
75	0.93
67	0.87
50	0.71

Leakage Factor (ν). — The leakage factor, i.e., the ratio of the total flux produced by the field to the flux which enters the armature, may be determined by calculating the permeance of the path of the armature flux and the permeance of the various leakage paths. The sum of the permeances of the main and leakage paths, divided by the permeance of the main path, is then the value of ν.

Referring to Fig. 3, the average radial depth of the air gap is approximately 1.25 g, and the reluctance of the gap is therefore 1.25 g/af. The reluctance to the useful flux of the iron part of the magnetic circuit is about 20 per cent of that of the gap in 60-cycle machines, and 40 per cent in 25-cycle machines. Hence the approximate value of the permeance of the path of the main flux is

$$P_0 = \frac{af}{1.5\,g} \text{ for 60 cycles, and } P_0 = \frac{af}{1.75\,g} \text{ for 25 cycles.}$$

The flux emanating from or entering each side of a pole has a path l_1 inches long and cf square inches in cross section. The permeance of this path to the plane midway between a pair of poles is $2\,cf/l_1$. There are two of these paths in multiple, one in each direction, from opposite sides of each pole. The total permeance of this path per pole is therefore $4\,cf/l_1$. If a uniform m.m.f. acted on this path at all points the flux would be proportional to this permeance, but since the m.m.f. varies from 0 at the yoke to the full m.m.f. per pole at the pole shoe, the average m.m.f. is one-half the m.m.f. per pole. The leakage flux through this path is therefore proportional to the m.m.f. per pole and to one-half this permeance. Hence the "effective permeance" of this path is

$$P_1 = \frac{2\,cf}{l_1}.$$

The same reasoning applies to the flux which leaks out from the end surface bc (see Fig. 3) of the poles, giving as the effective permeance of this path

$$P_2 = \frac{2\,bc}{l_1 + \frac{b}{2}} = \frac{2\,bc}{l_2}.$$

The leakage between the pole tips is due to the total m.m.f. per pole, and the permeance of this path is therefore

$$P_3 = \frac{4\,c_2 f}{l_3}.$$

The leakage from the faces of the poles at the chamfer is also due to the total m.m.f., and the permeance of this path is

$$P_4 = \frac{4\,c_3 f}{l_4}.$$

The leakage factor is then

$$\nu = 1 + \frac{P_1 + P_2 + P_3 + P_4}{P_0}. \qquad (3)$$

Ampere Turns. — The ampere turns required to produce the useful flux ϕ may now be calculated by the following systematized procedure. The symbols are: ϕ = useful flux per pole; ν = leakage factor; T = pole pitch; l = effective length of armature iron; s = pitch of slots at gap; D = diameter of armature at gap; D_1 = outside diameter of armature iron. Other dimensions as shown in Fig. 3. All dimensions are in inches.

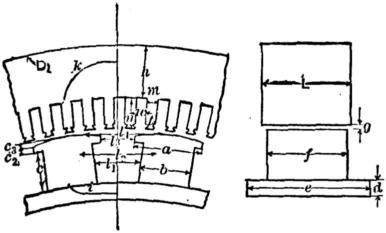

Fig. 3. Dimensions of Magnetic Circuit

Prepare a table like the following:

Part	Flux	Cross section, A	Flux density = flux/A	Ampere turns per inch, m *	Length of path, λ	Total ampere turns $= m\lambda$
Field yoke....	$0.5\,\nu\phi$	de	......	......	i	......
Field pole.....	$\nu\phi$	$0.95\,bf$	......	......	c	......

* The value of m is found from Fig. 4 when the flux density has been calculated.

Field Yoke. — The field yoke carries only half as much flux as the pole piece, as the flux divides at this point. The material is usually cast iron or cast steel. Find the magnetic density as indicated and refer to the proper magnetization curve to find the ampere-turns magnetizing force per inch for this density (see Fig. 4). The length of path is one-half the distance from the center of one pole to the center of the adjacent pole and is shown by i in Fig. 3. Find the total ampere turns as indicated.

Field Pole or Magnet Core. — This carries all the flux. The material is usually sheet steel of high permeability, but sometimes solid steel (formerly). The factor 0.95 is used for laminated steel poles; for solid poles this factor is of course unity. The length of this path is usually taken as c, the length of the space for the field spool. This is not strictly accurate, but the density in the pole shoe (c_2) is so low that the excitation required for this part is negligible.

Air Gap. — All the flux in the pole piece does not cross the gap, as some leaks across the interpolar space. The value of the flux in the gap is taken the same as the useful flux in the armature. For the area of gap section the cross

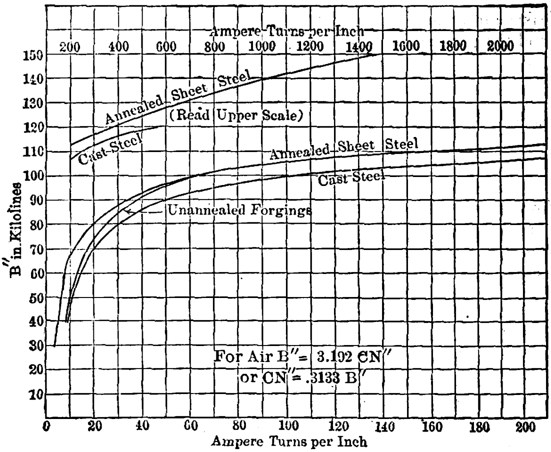

Fig. 4. Typical Saturation Curves

section (*af*) of the pole shoe is taken. The length of the path in the air gap is taken as the mean of the gap length. As the maximum length (at the pole tips) is usually made twice the minimum, and the outline of the pole face is made the arc of a circle, the average length is usually 1.25 times the minimum. The ampere turns per inch are 0.313 × (density per square inch).

The total ampere turns calculated as above indicated is sometimes multiplied by a constant (0.9 to 1.1), to allow for the spreading of the flux into the slots.

Armature Teeth. — The flux is confined at any one time to a certain portion of the teeth per pole known as "teeth under one pole." Since the flux spreads somewhat on leaving the pole piece it is logical to assume that it takes up a peripheral length equal to the pole arc plus twice the length of the air gap. If, therefore, this length is divided by the pitch of teeth at the periphery of the armature, the quotient is the average number of teeth carrying flux at any given instant. This figure may quite properly contain a fractional number of teeth. The teeth being wedge shaped or sectors of a circle, that cross section (not the mean cross section) which will give the average excitation must be chosen, since saturation increases more rapidly than the cross section decreases. A good approximate value is found at a point one-third the distance from the minimum width towards the maximum width.

The effective cross section of the teeth is then equal to this width multiplied by the product of the effective length of the core by the number of the "teeth under one pole." The effective length of core is the net length of iron in the core after deducting the space occupied by air ducts and insulation between sheets of steel. This latter is usually 10 per cent of the measurable length of iron. The effective length (l) = 0.9 × (total length of armature core less space occupied by ducts).

Armature Core. — The flux divides again in the armature core, one-half the useful flux being in each section of the armature core. The core is made of annealed sheet punchings. The cross section of core is equal to the radial depth of core back of the slots multiplied by the effective length of iron in the core. The length of path is a little greater than one-half the pitch of poles at this radius, and is as shown at (k), Fig. 3.

The total ampere turns per pole as thus calculated, corresponding to the chosen value of the voltage per phase give one point on the magnetization curve. As noted above, a sufficient number of points should be calculated in the same manner to enable one to extend the saturation curve up to about 120 per cent of rated voltage per phase.

Armature Resistance. — The length of wire in the armature winding is estimated from the mean length of one turn and the number of turns. Let L = total length of armature core in inches; γ = per cent pitch of coils; D = diameter of armature at gap; p = number of poles; S = number of turns in series per phase; a = cross section of conductor* (wire or strip); m = number of parallel paths per phase; k = 10 for low-voltage machines, and 12 for high-voltage machines (k allows for the curves in the ends of the coils). Then the mean length of turn is

$$l = 2L + \frac{k\gamma D}{p},$$

and the resistance *per phase* is

$$R = \frac{0.0093\, lS}{12{,}000\, am},$$

where 0.0093 is the resistance at 60° C. of 1000 feet of conductor having a cross section of 1 square inch. 60° C. is the approximate temperature of the armature conductors at full load.

This is the resistance per phase to a direct current. The alternating-current resistance, due to eddy currents and hysteresis, is about 15 per cent greater; see paragraph on *Load Loss*, below.

In a single-phase or two-phase machine this resistance is the same as the resistance between terminals. In a Y-connected three-phase machine the resistance between terminals is twice the resistance per phase. In a Δ-connected three-phase machine the resistance between terminals is two-thirds of the resistance per phase.

Armature Leakage Reactance. — The load current in flowing through the armature conductors sets up a local magnetic flux which interlinks with the armature conductors, producing inductance. This inductance causes a loss of voltage and a "dephasing" effect, or lag of current behind the e.m.f.

The inductance L of any circuit, expressed in henries, is

$$L = 1.016\pi S^2 P \times 10^{-8},$$

where S = number of turns in series,
P = permeance of flux path in inches.

The corresponding reactance is $2\pi fL$, where f is the frequency in cycles per second.

There are several paths for this so-called armature leakage flux, each path surrounding one or more slots, namely, the path around each slot, the path around a group of slots of one phase, the path around the end connections. The effect of the flux of one phase on the conductors of another (mutual inductance) must also be considered.

The slots lying under a pole have a path of greater permeance than those lying opposite the interpolar space or between poles, as the former are more completely surrounded by iron.

* If pressed cable is used, the cross section of the copper in the cable is approximately 82 per cent of the cross section of the cable, exclusive of insulation. The length of each of the wires forming the cable is about 7 per cent greater than the length of the cable.

With the exception of the path around the end connections, the permeance of each path is readily calculated by the same process as used above in calculating the leakage factor. The path around the end connections is so complex and the permeance so small compared with that in the core proper, that it is convenient and sufficiently accurate to add a percentage for this flux. This is done by allowing for every inch of the projecting length of the end connections one-tenth as much flux or inductance as for an inch of the embedded portion of the conductors.

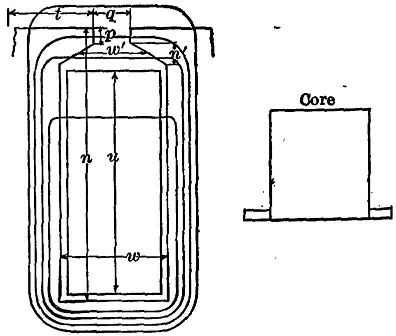

Fig. 5. Leakage Flux

In calculating the permeance of the various paths only the length of the path in air is considered, as the reluctance of the path in iron is so small compared to the path in air as to be negligible.

Let l = effective length of armature core; l' = length of end connections (one end); P_1 = the total permeance of all the leakage paths for a slot under a pole piece; P_2 = the total permeance of all the leakage paths for a slot midway between two poles, and the other quantities as in Fig. 5. Then

$$P_1 = \left(\frac{u}{3w} + \frac{n'}{w'} + \frac{p}{q} + \frac{t}{2g}\right)\left(l + 0.1\, l'\right)$$

$$P_2 = \left(\frac{u}{3w} + \frac{n'}{w'} + \frac{p}{q} + \frac{t}{t+q}\right)\left(l + 0.1\, l'\right)$$

In addition to the above symbols, let f = frequency in cycles per second; p' = the slots per pole per phase; s' = slots in series per phase; c = effective conductors per slot = $2 \times$ (turns per phase)/slots per phase; k_3 = "pitch constant" (*see above*). Then the effective reactance in ohms per phase corresponding to the permeance P_1 is

$$x_1 = 20.1\, f p' c^2 s' k_3 P_1 \times 10^{-8},$$

and corresponding to the permeance P_2 is

$$x_2 = 20.1\, f p' c^2 s' k_3 P_2 \times 10^{-8}.$$

Reactance Drop. — For preliminary or approximate calculations it is better and more conservative to use the value found for the inductance of the slots "under the poles," as this gives a greater reactance and voltage loss, and, as the poles usually cover about two-thirds of the armature periphery, this is nearer correct. That is, the armature reactance drop per phase is taken as Ix_1, where I is the armature current per phase.

For more accurate calculations both values must be used, and the power component and reactive component of the current considered separately. Let θ be the power-factor angle and I the armature current per phase. Then the reactive drop per phase is

$$IX = I\sqrt{(x_1 \cos\theta)^2 + (x_2 \sin\theta)^2},$$

which is therefore equivalent to taking for the effective armature reactance

$$X = \sqrt{(x_1 \cos\theta)^2 + (x_2 \sin\theta)^2}.$$

Armature Reaction. — When current flows through the armature the armature winding becomes the seat of a magnetomotive force which reacts on the field m.m.f. and either distorts or diminishes the useful flux. If the current in the armature is in phase with the generated e.m.f. it causes a "cross magnetizing" force acting along an axis passing midway between any pair of poles.

As the phase of the current in the armature changes, the direction of the magnetizing force due to the armature m.m.f. shifts, and a component is introduced either opposed to the field magnetizing force (for lagging current) or assisting the field magnetizing force (for leading current). In a polyphase generator the magnetizing force due to the armature m.m.f. for a given armature current is constant in magnitude and has a fixed direction with respect to the field magnetizing force, depending on the phase of the current.

If the field iron had no polar projections nor interpolar spaces, the direction of the armature magnetizing force would be such that the angle between this magnetizing force and a line perpendicular to the field magnetizing force would be equal to the phase angle between the induced voltage and current.

With the usual type of alternator having interpolar spaces the reluctance of the path offered to the armature m.m.f. is intentionally much greater than that offered to the field m.m.f. The result of this is that the effect of armature reaction is minimized. The non-uniformity of the field iron, however, changes the relative directions of the two magnetizing forces and renders accurate calculations difficult. As a rule, however, the approximation resulting from the assumption of uniform distribution of field iron is sufficiently accurate. The error introduced by this assumption is on the safe side, since the armature reaction as thus calculated is greater than its actual value.

Armature-Reaction Ampere Turns per Pole. — Let S = number of turns in series per phase; I = effective value of armature current per phase; p = number of poles, and k_3 = pitch constant of the winding (*see above under Magnetization Curve*). Then the armature ampere turns per pole effective in producing armature reaction are

$$\frac{\sqrt{2}\,k_3SI}{p}, \qquad \text{for two-phase machine,}$$

$$\frac{1.5\sqrt{2}\,k_3SI}{p}, \qquad \text{for three-phase machine.}$$

As noted above the armature reaction for a given effective value of the current is constant in magnitude. The armature reaction in single-phase generators is given in the discussion of these machines below.

The armature-reaction ampere turns of different machines at full rated load is greater for a high than for low pole pitch, and is less for high frequencies than for low frequencies. The permissible armature-reaction ampere turns depend, of course, upon the desired regulation.

A reasonable value for armature reaction would be between 1500 and 5000 ampere turns per pole for a 25 cycle machine and between 1000 and 2000 for a 60 cycle machine.

Synchronous Reactance. — The effect of the armature leakage reactance and armature reaction upon the terminal voltage of a generator at given field excitation are of like character, since the voltage induced in the armature due to each of these causes is in quadrature with the current. The "synchronous reactance" of a generator is the equivalent reactance which would produce the same effect as the armature leakage reactance and armature reaction combined.

The synchronous reactance may be predetermined by finding the excitation ampere-turns (from magnetization curve) corresponding to a voltage equal to

the drop due to leakage reactance and adding to these ampere turns the armature reaction ampere turns. The voltage from the magnetization curve corresponding to this sum divided by the armature current per phase gives the synchronous reactance per phase. In the calculation of regulation by the "magnetomotive force method" (see below), however, it is more convenient to express the synchronous reactance in terms of the excitation ampere turns to overcome it.

Regulation. — The regulation of a generator machine is defined as the ratio of the difference in terminal voltage at no load and at full load to the full-load voltage, the field excitation being kept constant at its full-load value. Expressed as a percentage the regulation is 100 $(V_0 - V) \div V$ where V is the full-load terminal voltage and V_0 the no-load terminal voltage at full-load field excitation.

Two different methods have been employed for the calculation of regulation, one known as the "magnetomotive-force" method, and the other as the "electromotive-force" method. Both are approximations, the first giving a value lower than the actual value, and the second a value higher than the actual value. More accurate methods have recently (1914) been recommended by the American Institute of Electrical Engineers (*see Standardization Rules*).

Magnetomotive-force Method. — One way in which this method has been applied is the following: Let V = terminal voltage per phase at full load; R = alternating-current resistance per phase in ohms (= 1.15 times direct-current resistance); I = full load amperes per phase; $\cos\theta$ = power factor of the load; X = leakage reactance per phase in ohms. Calculate

$$V' = \sqrt{(V\cos\theta + RI)^2 + (V\sin\theta + XI)^2} \quad \text{and} \quad \theta' = \tan^{-1}\left[\frac{V\sin\theta + XI}{V\cos\theta + RI}\right]$$

taking θ' positive for I lagging behind V'. From magnetization curve find m = excitation ampere turns corresponding to V' and let n = armature reaction ampere turns per pole for current I (see p. 635). The total field ampere-turns is then

$$F = \sqrt{m^2 + n^2 + 2\,mn\sin\theta'}.$$

Let V_0 = voltage per phase from the magnetization curve corresponding to this excitation F; then the regulation is

$$100\,\frac{V_0 - V}{V}.$$

The difference between V' and V and between θ' and θ is usually quite small, and in preliminary calculations m may be taken as the excitation ampere turns corresponding to V, and θ' may be taken equal to θ.

Electromotive-force Method. — Let V = terminal voltage per phase at full load; R = alternating-current resistance per phase in ohms (see preceding paragraph); XI = volts per phase from magnetization curve corresponding to the field excitation required to send full-load current through armature on synchronous impedance test; I = full-load amperes per phase; $\cos\theta$ = power factor. Then the voltage per phase E at no load, corresponding to the full-load excitation, is the vector sum of V, RI and XI, or

$$E = \sqrt{(V\cos\theta + RI)^2 + (V\sin\theta + XI)^2}.$$

The regulation is, as before, 100 $(E - V)/V$, and the full-load field ampere turns F is taken from the point corresponding to E on the magnetization curve.

Losses. — The losses in a synchronous alternating-current generator or motor are:

(a) Friction, bearing and windage.
(b) Excitation or field copper loss.
(c) Core loss.
(d) Armature copper loss.
(e) Load loss.

Of these the first three are approximately constant for various loads, but the last two vary as the square of the load current.

Friction and Windage depend in magnitude upon the details of the physical or mechanical construction, the amount of induced ventilation and speed. It is impossible to give a method of predetermining this quantity which will apply to various designs and makes. Each manufacturer has an empirical formula for each line of machines. This loss ranges from 2.5 per cent in 100 kv-a. machines to 0.5 per cent in 10,000 kv-a. machines. These values are for complete machines with their own bearings (two in number). Some machines are designed with only one bearing, the other bearing being a part of the prime mover (hydraulic or steam) in which case the friction chargeable to the generator is less. Some machines with devices to produce ventilation, such as fan blades attached to the revolving part, have greater friction losses.

Core Loss. — The core loss is made up of hysteresis and eddy-current losses. These losses are principally in the armature core and teeth, but if proper care is not taken there may be a considerable loss in the frame of the machine and the pole shoes.

It is a simple matter to calculate the magnitude of these losses in the armature core proper, as the frequency and flux density are definite in this part, but the losses in the teeth are due not only to the fundamental frequency and main flux, but also to pulsations due to the passage of pole tips past the teeth and the leakage flux of the armature. The total core loss is the sum of the hysteresis and eddy-current losses. See *Magnetic Properties of Iron and Other Metals* for curves of hysteresis and eddy-current losses and formulas for their calculation.

Excitation Loss. — The calculation of the field current and of the resistance per pole of the field winding is given above in the section on *Field Winding.* The total power required for excitation will be the product of this resistance, the square of the current and the number of poles.

If the machine is separately excited, which is usually the case, the losses in the field rheostat are, by convention of the Am. Inst. of E. E., not chargeable against the generator.

Armature Copper Loss. — The calculation of the direct-current resistance per phase of the armature winding is given above in the section on *Armature Resistance.* The total armature copper loss is equal to the number of phases times this direct-current resistance times the square of the current per phase.

Load Loss. — When a current flows in the armature conductors a local flux is set up which will cause eddy currents in these conductors, if they are not well subdivided, and in the surrounding iron, as well as a hysteresis loss in the surrounding iron. The loss due to this load flux is called the "load loss."

The load loss is a function of the leakage flux and the subdivision of the conductors. A large number of turns of fine wire will involve a very small loss. If the conductors must be large, they may be made of stranded cable pressed to shape. It is almost impossible to calculate this loss, and very difficult to measure it. A rough method is to assume the resistance per phase increased by 15 per cent, as this loss, like the true copper loss, is proportional to the square of the armature current. The total amount of the loss is less than 1 per cent of the input in well-constructed machines.

Efficiency. — Let P = total output in kilowatts; R_a = resistance per phase of armature; I_a = armature amperes per phase; R_f = resistance per pole of field winding; I_f = field current; q = number of phases; p = number of poles; C = total core loss in kilowatts; and F = friction and windage loss in kilowatts. Then the per-cent efficiency is

$$\frac{100\,P}{P+C+F+(1.15\,R_a q I_a^2+pR_f I_f^2)\times 10^{-3}}.$$

This assumes the load loss equivalent to increasing the armature resistance (as calculated or measured by direct current) by 15 per cent. If the load loss is determined from the short-circuit core loss the formula for efficiency is

$$\frac{100\,P}{P+C+F+L+(R_a q I_a^2+pR_f I_f^2)\times 10^{-3}},$$

where L is the load loss in kilowatts.

The efficiency is a maximum for that load at which the constant losses are equal to the variable losses.

Customary values for the efficiency at full load and each of the losses at full load for various sizes of generators are given in the following table. These values are merely indications and vary with the frequency, voltage, speed, power factor, etc. A 60-cycle low-voltage machine will be likely to have a better efficiency than a machine of the same rating for 25 cycles or high voltage.

EFFICIENCY AND LOSSES, USUAL VALUES

Rating, kv-a.	Efficiency, per cent	Friction, per cent	Excitation, per cent	Core, per cent	Armature,* per cent
100	91	2.5	2.5	2.4	1.6
500	94	1.4	1.5	2.2	1.2
1,000	95	0.9	0.9	2.1	1.0
2,000	96	0.6	0.7	1.8	0.9
3,000	96.5	0.6	0.6	1.7	0.8
5,000	97	0.55	0.4	1.6	0.5
10,000	97.2	0.5	0.35	1.5	0.45

* Copper and load loss.

Heating. — The rise in temperature of the field coils is ascertained as an incidental step in the calculation of the field winding as explained above.

The rise in temperature of the armature is best determined by a method given by Arnold (*see Wechselstromteknik, Vol. IV, p. 141*). In this calculation the losses in the projecting portions of the end windings are assumed to be radiated by the end windings while the core loss and copper loss in that portion of the winding embedded in the slots are radiated by the surface of the armature core. Let L = length of armature iron in inches; λ = mean length of armature turn in inches (*see Armature Resistance, below*); R_a = armature resistance per phase in ohms; I_a = armature amperes per phase; D_1 = outside diameter of armature punchings in inches; D = inside diameter of armature punchings; z = number of ventilating ducts; q = number of phases; t = rise in temperature in degrees centigrade per watt radiated per square inch of surface. Then the watts to be radiated are

$$P = \text{core loss} + \frac{2\,LqR_aI_a^2}{\lambda},$$

and the radiating surface, including only one-half the area in the air ducts, as the sides of the air ducts are not as effective as the rest of the surface, is

$$A = \pi L (D_1 + D) + \frac{\pi}{4} (D_1^2 - D^2)(2 + z).$$

The rise in temperature by resistance in degrees centigrade is then

$$T = \frac{Pt}{A}.$$

The value of t for a well-ventilated stationary armature ranges from 30 to 40, depending upon the thickness of coil insulation, and the peripheral speed of the field. For a stationary field and revolving armature the value of t given above for the rise in a revolving field may be used.

SINGLE-PHASE GENERATOR. — Single-phase generators do not make as effective use of the material as do polyphase generators, for the reason that the armature winding can occupy effectively only about one-half of the peripheral surface of the armature; if it occupies more than this there will be voltages generated in the windings which are so out of phase with each other that the resultant voltage is only from 63 to 70 per cent of the sum of all the voltages generated.

Therefore, if a polyphase generator is used as a single-phase machine with the same magnetic densities and the same copper densities, the output will be much less on account of the lesser voltage available. It is, therefore, customary to overload the magnetic elements of the machine somewhat to raise the voltage and thus reduce the overload on the copper which would be necessary to get the desired output. However, if both the iron and copper densities are increased until the machine gives as much output single phase as it is intended to give polyphase, there will be an increased heating. Thus, for the same heating, obtained by a readjustment of the iron and copper losses, a machine of a given first cost will give about 75 per cent as much output single phase as may be obtained polyphase.

In addition to the disadvantage of a single-phase generator that it cannot make use of all the periphery of the armature, it also labors under the disadvantage that its armature reaction is pulsating instead of constant, and this introduces an additional loss in the form of eddy currents.

By using two phases in series of a three-phase machine, or one phase of a two-phase machine, a fairly good single-phase machine is obtained. By arranging the winding slightly differently the same number and arrangement of inductors (or coil sides) can be connected up to give a simpler winding requiring no crossings of coils, that is, a winding "in one plane."

The formula for the calculation of the e.m.f. of a single-phase generator is $E = 4.44\ k_2k_3fS\phi\ 10^{-8}$, where the symbols, with the exception of k_2, have the same significance as in the formula for polyphase machines, p. 629. The value of k_2 depends upon the portion of the armature periphery (including the teeth between slots) occupied by the main winding. Let A = this fraction of the armature surface, then the corresponding values of k_2 are given in the accompanying table. The value of A corresponding to a uniformly distributed winding is unity.

A	k_2
1	0.63
¾	0.785
⅔	0.83
½	0.90
⅓	0.956

The average value of the armature-reaction ampere turns per pole of a single-phase machine is SI/p, where S = the number of turns, I = the

armature current per phase, and p = the number of poles, but this quantity pulsates between 0 and twice the above value. The evil effects of this pulsating may be reduced by employing a short-circuited winding having its axis at 90 degrees to the main field winding. A squirrel cage or "amortisseur" winding in the pole faces is frequently employed for this purpose.

Due to this pulsating action the load losses are greater and this should be taken into account in calculating the efficiency and regulation by considering the effective armature resistance as 1.15 to 1.5 times the direct-current resistance.

The leakage reactance of a single-phase machine pulsates between a value equal to that obtained by the formula above in the paragraph on *Armature Leakage Reactance*, and a value two-thirds as great. Satisfactory results are obtained by multiplying the value obtained from the formula by 0.85 for the effective single-phase value. In this case the whole winding is considered as one phase.

CHECKING CALCULATIONS.—Substitution in the following formula gives an excellent check on the above calculations:

$$\frac{DL_f}{Q} = \frac{KA \times 10^9}{fB_g nak_2k_3},$$

where D = diameter of armature at gap in inches; L_f = length of pole face parallel to shaft; Q = total kv-a. of generator; f = frequency in cycles per second; n = armature-reaction ampere turns; a = pole arc in inches; k_2 and k_3 = constants (given in the tables on pp. 629 and 639); A = diameter per pole in inches; B_g = flux density, lines per sq. in. in air gap; and K = 22.5 for single-phase and 15.9 for two-phase or three-phase generators.

TESTS OF ALTERNATING-CURRENT GENERATORS.—(*See also Standardization Rules of the A.I.E.E.*) The principal tests are

- Magnetization or saturation test;
- Core-loss and friction tests;
- Synchronous-impedance test;
- Load-loss test;
- Resistance measurements;
- Heat runs;
- Insulation tests.

Examples of test results are given below; typical test curves are given in Fig. 6.

Magnetization Curve.—The magnetization curve, popularly named the "no-load saturation curve," shows the relation between the no-load voltage and the current in the field. Fig. 7 shows the connections for making this test. On account of the existence of the hysteresis loop (*see article on Magnetic Properties of Iron*), it is necessary, in running this test, to increase the field current gradually from point to point and never reduce the value at any step until the highest excitation has been obtained. The curve differs in shape from the magnetization curve of a closed sample of iron because the magnetic circuit of the alternator contains a considerable air gap, the magnetization curve of which is a straight line. Therefore, if the saturation curve of a machine contains a portion which is very straight, the indications are that the air gap is of considerable magnitude. If the machine is operated at very high magnetic densities, this is indicated by the fact that the point corresponding to rated voltage is found at a point on the curve where it is nearly horizontal.

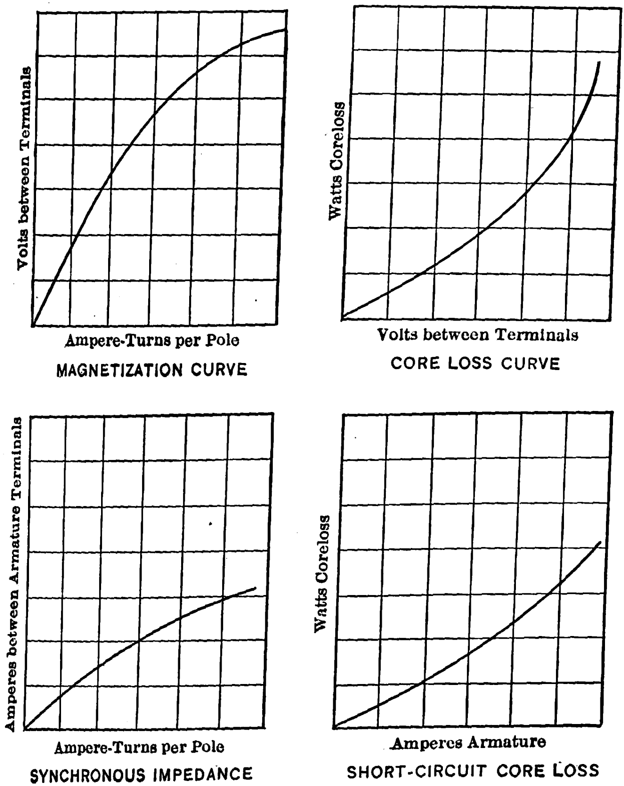

Fig. 6. Typical Test Curves

Some machines obtain good regulation by operating at high saturation, as this is a cheaper method than by using a low value of armature reaction and leakage reactance.

The magnetization curve is usually plotted in terms of the volts between terminals. In comparing the observed and calculated magnetization curve it should be noted that the calculations are expressed in terms of the volts per phase.

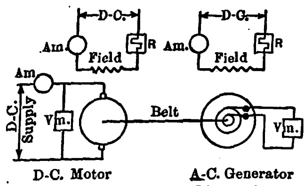

Fig. 7. Connections for Magnetization Curve, Core Loss and Friction Tests

Core Loss and Friction. — The open-circuit, or true core loss curve shows the core loss in watts for each value of the no-load terminal voltage. It is made by driving the generator at rated speed by means of a small motor, the efficiency of which is known, and varying the generator excitation. Fig. 7 shows the connections for this test. The voltage and mechanical power *P*

(= input to motor multiplied by its efficiency) required for each value of excitation are noted. The power P_0 for zero excitation is the friction loss in the machine. The core loss for any excitation is $P - P_0$. The no-load saturation curve can be made at the same time as the core-loss test.

Synchronous Impedance. — The synchronous-impedance curve shows the relation between various values of field current, or excitation ampere turns, and the current that flows in the armature on short circuit. It is made by short circuiting the armature through ammeters and operating at full frequency with various values of field current. Fig. 8 shows the connections for this test. Of course only fractional values of normal excitation are used, or the current in the armature would be so great as to cause damage.

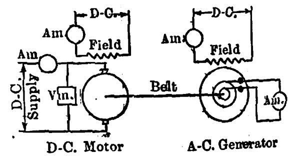

Fig. 8. Connections for Synchronous Impedance and Load-loss Tests

The synchronous-impedance curve gives approximately the ampere turns corresponding to armature reaction and the leakage reactance drop in the armature combined, i.e., the ampere turns corresponding to the synchronous reactance. The approximation arises from the effect of the armature resistance and the low saturation or magnetization of the magnetic circuit under the short-circuit conditions.

Load Loss. — The power dissipated in the core and armature conductors under short-circuit conditions, called the "short-circuit core loss," may be made at the same time as the preceding test, by measuring the power required to drive the machine under the same condition, proper allowance being made for friction. From this test the load losses for normal load conditions are assumed, as recommended in the *Standardization Rules of the A.I.E.E., 1911 Edition,* to be, for a given armature current, one-third of the value found with the same current in the short-circuit test. This is reasonable, since the armature current is considerably out of phase, which condition magnifies the losses. Another approximation to the load loss is to assume the "effective" resistance of the armature to be 1.15 times the d-c. resistance. In the standardization rules of the *A.I.E.E.* issued in 1914 the allowance for load loss (called the "stray load loss") is differently treated; see *Standardization Rules of the A.I.E.E.*

Resistance Measurements must be made when all parts of the machine are at some known temperature. They are also made after the heat run, when the machine is hot, to check the temperature as measured by thermometers (*see article on Resistance and Conductance*).

Field Resistance is measured by the simple voltmeter-ammeter method (*see article on Resistance and Conductance*).

Armature Resistance. — The armature resistance between terminals is also measured by the simple voltmeter-ammeter method, by connecting two of the terminals to a source of direct current (the other terminal being free), the rotor (field or armature) of course being at rest. In the case of a single-phase or two-phase machine the resistance as thus measured is the resistance per phase. In the case of a three-phase machine, let R_t = the resistance as thus measured and R_p = the resistance per phase. Then for a Y-connected armature $R_p = R_t \div 2$, and for a Δ-connected armature $R_p = 3\,R_t \div 2$. If the connection is not known, the calculation of the resistance drop and copper loss may be figured correctly assuming it either Y or Δ connected, provided the resistance per phase and current per phase are both calculated on the same assumption regarding the connection. In the case of a two-phase machine the

resistance between terminals A and B and between B and C (B being the common terminal) should each be measured, and the average taken. In the case of a three-phase machine the resistance between A and B, B and C, and A and C should be measured and the average taken.

Calculation of Regulation and Efficiency from Tests. — From the results of the preceding observations, the regulation and efficiency of the machine at various loads may be calculated by the methods given above, in the discussion of *Predetermination of Performance*, using the test data instead of the calculated quantities. The synchronous-reactance ampere turns may be taken as equal to the synchronous-impedance ampere turns, since the resistance drop in the armature on short circuit and reduced excitation is seldom over 10 per cent of the synchronous-reactance drop, and as the two are in quadrature the synchronous-impedance drop differs from the synchronous reactance drop by less than one per cent. In using the magnetization curve and the synchronous-impedance curve one must keep in mind whether they are plotted in terms of voltage and current per phase or in terms of volts between lines and line current.

Full-load Saturation Curve. — This curve shows the relation between the terminal voltage and field current with full-load current in the armature. It may be plotted from tests or calculated from the magnetization curve and the synchronous impedance in the same manner as the regulation is calculated.

Armature Leakage Reactance. — There are three methods by which the leakage reactance may be determined:

(1) **Synchronous-impedance Method.** — This gives only approximate results but is very generally used as a synchronous-impedance test is made on every generator. Let n be the field ampere turns per pole required to force full-load current through the short-circuited armature. Let a be the calculated armature-reaction ampere turns per pole (see above), with rated current. Then $n - a$ is the excitation necessary to induce the leakage reactance voltage (IX) in the armature. From the open-circuit saturation curve find the voltage corresponding to $(n - a)$ ampere turns. Reducing to volts per phase, if necessary, and dividing by the current per phase, the result is the leakage reactance X per phase in ohms.

(2) **Full-load Characteristic Method.** — This method is also approximate. Let the excitation in ampere turns per pole required to give rated voltage at full non-inductive load be q. Let the ampere turns to give rated voltage without load be m. Then $n = \sqrt{q^2 - m^2}$ is taken as the synchronous-reactance ampere turns, and the leakage reactance is calculated as described in the preceding paragraph.

(3) **Inductance-measurement Method.** — This method gives exact values, but is not very often employed. From an external source of proper frequency, full-load current is sent through the armature of the machine to be tested, with the fields excited to the normal value but not rotating. The voltage drop across the armature terminals is measured for several different positions of the coils with respect to the poles, ranging through an arc of about one-half the pole pitch. Let Z = the voltage per phase divided by the current, R = the resistance per phase corrected for load loss (i.e., 1.15 times the direct-current resistance), then the leakage reactance per phase is $X = \sqrt{Z^2 - R^2}$. This reactance will vary with the position of the coils and the maximum and minimum may be found by making this calculation for the different positions of the coils with respect to the fields.

Heat runs are made at rated load and various other specified loads. The parts in which the rise in temperature is of interest are:

Armature core surface;
Armature core ventilating ducts;
Armature conductors;
Collector rings;
Both pole tips;
Field winding;
Bearings;
Frame;
Room.

The temperature of the field and armature winding should be measured both by thermometers and by the resistance method. In taking the temperature of a hot surface by thermometer a small pad of waste should be placed over the bulb after the thermometer is put in place. The pad should not be too large or it will prevent the normal radiation from the surface.

With large machines it is inconvenient and expensive to test under full-load conditions. For determining the heating without actually developing the full power of the machine there are several methods available.

Reversed-field Method. — The field circuit may be tapped and the full-load field current sent through a portion of the field coils in a direction opposed to that for normal operation. For example, in a 24-pole machine the current in 8 of the field coils may be directed in such a manner that they are reversed with respect to the remaining 16. The armature winding will therefore generate a voltage due to the 8 poles that are not neutralized and therefore of approximately one-third rated value. If the armature is short circuited a current will flow due to this reduced voltage, and this current can be made to approximate closely the full-load value by making a proper division of the poles. If the machine is operated under these conditions the friction, excitation, core loss and armature copper loss will be very nearly equal to their value under normal operating conditions, yet to drive the machine only an amount of power approximately equal to the sum of the losses is required.

Synchronous-motor Loading. — If two machines are available they may be connected up as a generator and synchronous motor and the field excitation of the motor adjusted so that a current of full-load value, but having a large reactive component, will flow in the armature, the power factor being nearly zero. The power required to drive the generator at full-load excitation and at full-load current will then be small.

Direct-current Loading. — Full-load losses may be simulated on a three-phase generator by connecting the three phases in delta and leaving the delta open at one point, to which a direct-current ammeter and a source of direct current may be connected in series. The delta is first closed through an alternating-current ammeter and the triple-frequency current in the delta (*see Alternating Currents*) is measured. The direct-current ammeter and source of direct current are then connected in series with the delta and the direct current increased until the sum of the squares of the local current of triple frequency and the direct current is equal to the square of the rated current per phase.

Open-circuit Short-circuit Method. — Another ingenious method, advocated by Hobart, consists in alternating open-circuit and short-circuit tests, each under exaggerated conditions, so that at the end of each hour the total watt hours lost in each part are equal to the watt hours that would be lost in normal operation. For example, let the core and field copper loss be 4 kilowatts, and armature copper loss 1 kilowatt. If, now, the machine is operated for 20 minutes with armature short circuited and the excitation adjusted to give 3 kilowatts copper loss, and for 40 minutes on open circuit with excitation

adjusted to give 6 kilowatts core and field copper loss, then the loss per hour in the armature copper is 1 kw.- hr., and in the field winding and core 4 kw.- hr., the same as under normal conditions. For an exact division of the time between the open-circuit and short-circuit conditions, the core and field copper loss during the short-circuit run must be taken into consideration. After several hours of this relaying the machine will have reached a temperature corresponding to full-load operation.

Insulation Tests. — The insulation of a machine is usually tested by applying a given voltage between the conductors and the part of the machine from which they are insulated. An insulation resistance test is also made.

Voltage Tests. — During manufacture the coils are tested separately, and after the machine is assembled a voltage test between the completed windings and frame is made. After the heat run, while the machine is still warm, a third test of the insulation between windings and frame is made.

For this third test an alternating voltage is applied between armature and frame, according to the *Standardization Rules of the A.I.E.E.* (q.v.)

The voltage should be increased gradually and the final value should be applied for one minute. In this test the machine acts as a condenser and therefore care should be taken that the frequency is not so high or the inductance of the supply circuit so great as to set up resonance. It is advisable to have considerable resistance in the supply circuit.

To prevent an uneven distribution of voltage, all the terminals of the winding should be connected together by fine wires and one terminal of the high-potential circuit connected to the common connection. The high potential should be measured by a spark gap connected in shunt to the machine.

Insulation Resistance. — The insulation resistance is measured by connecting one terminal of a 500-volt direct-current supply to the windings of the machine through a voltmeter with a 500 scale, and connecting the other 500-volt terminal to the frame. If the resistance of the voltmeter is R_v ohms and the voltmeter deflection x, the insulation resistance is $R = \frac{R_v}{x}(500 - x)$.

EXAMPLES OF DESIGN AND PERFORMANCE. — In the tables on pp. 646 and 647 will be found the essential data both of the mechanical and electrical features of four representative alternators. The list of items will be found useful as a guide in collecting data on various machines. Performance data are deduced from tests.

OPERATION. — In the operation of an alternating-current generator the following factors should be considered:

Phase Connections and Grounding. — When a third harmonic is present in the e.m.f. wave of a three-phase generator, the triple frequency e.m.f.'s in the three phases (or windings) are additive when the three phases are connected in Δ, that is, the Δ forms a short circuit to the third harmonic e.m.f.'s, and a large triple frequency current may therefore be set up in the windings irrespective of the load on the machine. On this account, large three-phase generators are usually Y-connected, since with this connection the third harmonic e.m.f.'s between any two terminals of the machine neutralize each other. However, when two or more Y-connected machines are operated in parallel with their neutrals grounded, a triple frequency cross-current of considerable magnitude may be set up between the machines, unless the wave form of the e.m.f.'s of the various generators are exactly the same, which is practically never the case. To prevent such cross-currents with Y-connected machines with grounded neutral, it is the usual practice to ground the neutral of but one generator at a time. Provision must of course be made to shift this ground connection from one ma-

chine to any other, so that a ground connection can always be maintained irrespective of which machine or group of machines may be running.

The advantages and disadvantages of grounding the neutral are discussed in the article on *Grounding of Electric Circuits*.

Division of Load between Alternators in Parallel. — The division of load between two or more alternators operating in parallel cannot be changed by altering their field excitation, as is the case with direct-current generators. Changes in the load taken by any alternator of a group can be effected only by admitting more or less steam to the driving engine or turbine (or water to a water-wheel). In order that the various alternators shall share the combined load properly, it is therefore necessary that the governors on the several prime movers give the same speed-load characteristics.

Although the field excitation has no effect on the distribution of the load among the alternators, it does affect the power factor of the load delivered by each machine. The excitation of each alternator should be so adjusted that it delivers its load at the same power factor as the others.

Starting a Single Generator. — Before a generator is started up its bearings must be inspected and cleaned and filled with oil if necessary. The machine is then brought up to the proper speed and the bearings again inspected to see that the oil-rings are running properly. The exciters or excitation circuit is then put in readiness and the rheostat in the alternator field circuit adjusted for maximum resistance. Before exciting the field the armature insulation must be thoroughly dry. If it is not the armature is short-circuited through an ammeter and run for several hours at a partial excitation to give about rated current in the short-circuited armature. When the insulation is thoroughly dry the short-circuit is removed and the excitation adjusted to give rated voltage at the armature terminals with correct speed. To shut down the machine the load is first removed by opening the circuit breaker; then the field rheostat is turned to

maximum resistance as is also the rheostat in the exciter field if there is an individual exciter. Then the field circuit is opened.

Paralleling of Generators. — Before connecting a generator to bus bars to which one or more other generators are connected, the following conditions must be satisfied:

1. The frequency of the generator must be the same as that of the bus bars.
2. The frequency of the generator, and therefore its speed, must be constant for an appreciable interval of time.
3. The voltage of the generator must be the same as the voltage of the bus bars.
4. The generator and bus-bar voltage must be in phase.

If the two machines have not the same frequency or if the frequency is not constant, a condition will occur intermittently in which the two voltages are 180° apart or the two machines are in series on a short circuit, and a dangerous current will flow. If the voltages are not equal, a large "wattless" or reactive current may flow, and if the two voltages are not in phase, a large power current will flow which will cause a mechanical shock. To indicate when these conditions are fulfilled any one of several "synchronizing" devices may be employed, as described in the article on *Synchronizers and Synchroscopes*.

Synchronizing with Lamps. — The simplest method of synchronizing small machines is to use incandescent lamps as shown in Fig. 9. In Fig. 9A, the connections are such that the lamps remain dark when the above conditions are satisfied, while in Fig. 9B they will remain bright under these conditions. If the frequencies are wrong the lamps will flicker (the slower the flicker the nearer the two frequencies). If the voltages are wrong the lamps in 9A will glow slightly but steadily. Transformers should be used with the lamps in case of high-voltage machines.

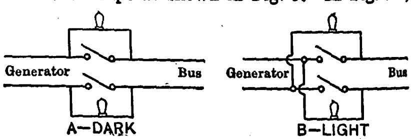

Fig. 9. Connections of Lamps for Synchronizing

Hunting. — Unless the angular velocities of two machines which are connected in parallel remain the same, either both constant or both varying together, a cross current will flow, due to the phase displacement between them. This current will tend to drag ahead the machine which is lagging, but due to the inertia of the rotating parts the machine which is at first lagging will "overreach" and become leading, and under certain conditions a cumulative see-saw action will be set up. When this takes place the machines are said to "hunt." The value of this current is proportional to the short-circuit current of the machines and to the angular displacement expressed in electrical degrees. In a machine having a large number of poles (40), a very small variation in angular velocity of the prime mover may cause a considerable (20-fold) phase displacement in electrical degrees.

To prevent hunting it is necessary to have:

1. A prime mover giving reasonably constant tangential effort and angular velocity. In general, the maximum variation in angular displacement between any machine and the bus bars should not exceed 2.5 electrical degrees.

To secure this condition the machines should have constants such that they are not especially sensitive as pendulums to the strokes or impulses of the particular engines used.

2. A governor which is not too sensitive to slight and sudden variations in load, i.e., a damped governor.

3. A low-resistance drop (usually not over 10 per cent) in the connections between the machines. This refers particularly to groups of machines in power houses miles apart.

4. Short-circuited or "Amortisseur" windings on the fields of the machines. Currents induced in these windings cause them to act as electrical brakes.

Short Circuits. — An alternator when suddenly short circuited will deliver for an instant a current many times as great as will flow after conditions have become constant. This is due to the fact that it takes a finite period of time for the increased armature reaction to weaken the magnetic field. During this short period much damage may be done to circuit breakers, etc. This is especially true of large turbo-alternators, as these, due to their construction, have a very large short-circuit current.

Use of External Reactance. — It is therefore frequently the case that reactance or choke coils are connected in circuit with these machines to prevent a dangerous current flowing in case of sudden short circuit. See *Reactance Coils.*

Induction Generators on Short Circuit. — Induction generators are free from this fault, since they lose their excitation almost immediately on short circuit, and are therefore becoming popular in large central stations.

Use of Imbedded Thermometers. — In large generators thermocouples or resistance thermometers (*see Pyrometers*) are sometimes embedded in the estimated hottest spot of the winding, and connected to a suitable indicating device to show at all times the maximum temperature of the machine. See also *Standardization Rules of the A.I.E.E.*

SPECIFICATION FOR A-C. GENERATOR.* — The following memoranda are intended to assist in writing specifications. See also article on *Specifications.*

Principal Characteristics and Conditions of Service. — Service for which generator is to be used, such as a-c. lighting, single-phase railway service, operating railway or lighting synchronous converters, etc. Voltage and number of phases. Rated output in kilowatts or kilovolt amperes at stated power factor. Frequency and speed.

Style and Description; Details of Construction. — Type of generator, revolving field, induction type, etc. Details of speed, governing of prime mover, and how generator is connected to prime mover, e.g., direct or belt-driven by steam turbine, reciprocating engine, water wheel, water turbine, gas engine, oil engine, etc., with vertical or horizontal shaft. Whether compensated. Whether exciter is to be supplied; if so, its characteristics. If field rheostat is to be supplied, its characteristics, including the effect upon the generator voltage of each step and of all steps; whether to be controlled by hand or automatically. Restriction of excitation current and voltage and requirements respecting carrying capacity of slip rings. Accessibility of armature. Maximum length of armature conductor projecting from slot. Windings shall be clamped securely to prevent any vibration of overhanging parts. Mechanical protection of armature conductors if exposed. If belt driven, specify pulley details; whether bed plate is desired.

Work to be Done by Other Contractors. — Whether Contractor is to furnish and install the following. Main wiring, field wiring, field rheostat grids, dial plate and chains. Point of division between engine and generator contracts.

* By W. A. Del Mar.

Performance and Tests. — (*See Standardization Rules of the A.I.E.E.*). Temperature rises upon which ratings are to be based. Details of overload capacity. Efficiency at 25, 50, 75, 100, and 125 per cent load. High-potential tests of insulation. Requirements regarding effects of moisture upon insulation. Requirements for parallel operation, i.e., whether the machine is to operate in parallel with similar machines or different ones. It is usual to specify that the terminal voltage shall vary according to a sine law. Regulation with 100 per cent power factor and normal speed; the load may be varied from zero to 150 per cent of rated load without causing more than a stated variation of voltage, the exciter field being kept constant.

DIMENSIONS, WEIGHT AND COST. — While generators vary widely in their specific weights and costs, that is weight per kv-a. rating, and cost per kv-a. rating, they may be divided into classes in which these characteristics are fairly definite.

The conditions primarily affecting the specific weight are: method of rating, speed, frequency, voltage and size. In addition there are the peripheral speed and mechanical construction which cannot be easily classified. The method of rating is fundamental. For purposes of comparison the rating may be taken as the output in kv-a. which each machine will give continuously with a rise in temperature not exceeding 45° C. On this basis the specific weight decreases as the speed, frequency or capacity increases, and increases with increase of voltage. The cost per pound decreases as the frequency decreases, and as the capacity increases. The cost per pound increases as the voltage and peripheral speed increase.

Alternating-current generators may be divided into three classes according to their speeds and purposes:

High speed, as turbine-driven generators.
Medium speed, as belt-driven and water-wheel-driven.
Slow speed, as engine-driven generators.

Approximate over-all dimensions of typical 60-cycle three-phase generators of various ratings for each of the above classes are given in the table below. The dimensions and weights for the turbo-generators include both the turbine and the generator. The voltages given in this table are the highest values for which the given size of a standard line is wound. Lower standard voltages are obtainable readily.

Approximate weights, costs per kv-a. and suitable speeds are indicated in Fig. 10 for engine-driven and in Fig. 11 for water-wheel-driven 60-cycle, 2300-volt, polyphase machines. The weight and cost of 25-cycle generators are from 10 to 20 per cent greater than for 60-cycle generators. The cost of machines for less than 2300 volts is practically the same as for 2300-volt equipment. Two-phase generators weigh and cost practically the same as three-phase. Single-phase generators weigh and cost from 25 to 30 per cent more. These data are of course suitable only for preliminary estimates; the costs, particularly, are subject to large variations due to changes in commercial conditions from year to year. For final estimates exact dimensions and quotations should be obtained from the manufacturers.

[W. I. SLICHTER.]

GENERATORS, DIRECT-CURRENT. — (*See also Alternating Currents; Electricity and Magnetism, Principles of; Generators, Alternating-Current; Motors, Direct-Current; Standardization Rules.*)

The following is a brief outline of the contents of this article:

APPLICATIONS. — Direct-current, or, as it is sometimes called, continuous-current apparatus was in very general use before the alternating-current type was introduced, and wherever the distance to which energy is to be transmitted is not a factor, there is no doubt that the direct-current system is to be preferred. However, if energy is to be transmitted over long distances the alternating-current system with its transformer has unequivocal advantages. The result of these two conditions is that a compromise is adopted. The majority of the generating stations provide alternating currents and many of the motors use direct currents provided by rotary converters. Thus the direct-current generators are becoming of less relative importance while the direct-current motors maintain a very important position.

Series Machines. — A series machine, generator or motor, is one in which the entire armature current flows through the field winding. Series generators are usually built to supply a constant current to an external circuit irrespective of the effective resistance of that circuit.

DEFINITIONS. — The fundamental principle involved in the construction and operation of any type of dynamo-electric machine is the production of an electromotive force in one or more conductors by the relative motion of these conductors and a magnetic field. Such a machine may, as a rule, be used either as a generator or motor.

Shunt Machine. — A shunt machine, either generator or motor, is one in which the entire field excitation is derived from a circuit of many turns and high resistance connected in "shunt" or multiple with the armature circuit. The characteristic of a shunt machine is poor regulation; that is, the voltage of a shunt generator decreases as the load increases. This is so marked that some shunt generators may be short-circuited, their terminal voltage dropping to zero, without resultant harm.

Separately Excited Machine. — This type of machine is sometimes used in large stations where the exciting current is readily obtained from separately excited bus-bars and a voltage regulator is used.

Compound-wound Machine. — This type of machine has on each field pole in addition to its shunt winding a few turns of thick wire which carry the load

current and are known as the series winding. This winding causes the excitation to increase as the load increases and tends to keep the terminal voltage constant or even to increase it. If the field windings are proportioned to cause the voltage at full load to be higher than the voltage at no load the machine is said to be "over-compounded." A "flat compounded" machine has the same voltage at full load and at no load; an "under compounded" machine has a lower voltage at full load than at no load.

Short- and Long-shunt Connections. — A compound-wound machine may be connected short shunt as in Fig. 1 or long shunt as in Fig. 2. The choice is merely a matter of convenience of station wiring.

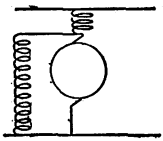

Fig. 1. Short-shunt Connections

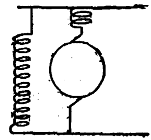

Fig. 2. Long-shunt Connections

Commutating Pole or Interpole Machines. — These machines have small auxiliary poles alternately placed with respect to the main poles and excited by a few turns in series with the load. The effect of these poles is to improve the operation of the machine in the matter of commutation; see below.

Bi-polar Machines. — Small continuous-current machines are usually of the bi-polar or two-pole type with a more or less inclosed frame of cylindrical shape.

Multi-polar Machines. — Large direct-current machines are of the multipolar type, that is, have a large number of radial pole pieces.

Belt-driven and Direct-connected Types. — Direct-current generators may be of either the "belt-driven" or the "direct-connected" type, as determined by the method of connecting to the driving unit. Belt-driven generators are characterized by a higher angular velocity than direct-connected.

RATINGS. — It has been common practice (up to 1914) to rate direct-current machines on the basis of the output in kilowatts which they will give continuously with a maximum rise in temperature by thermometer of 50° C. above the surrounding air at 25° C. See however the recent recommendations of the A.I.E.E. in the article on *Standardization Rules*.

VOLTAGE. — The standard voltages for which continuous-current machines are built are:

80 volts for use on shipboard.
110–125 volts for lighting purposes and incidental small power motors, fan motors, cooking utensils.
220 volts for three-wire systems with lighting and power combined.
500–600 volts for power alone and particularly for railway service.
1200–2400 volts for special railway service and heavy traction.
2000–6000 volts for series-arc-light circuits fed by series machines.

ELECTROMOTIVE FORCE INDUCED IN ARMATURE. — Let

Z = total number of armature conductors or sides of coils.
p = number of field poles.
m = number of parallel conducting paths between the positive and negative brush sets; that is $\frac{Z}{m}$ is the number of armature conductors in series between positive and negative brush sets. (*See below under Armature Windings.*)

ϕ = total useful magnetic flux per pole.
N = revolutions of armature per minute.
f = frequency in cycles per second.

If a coil of wire be revolved about an axis in a magnetic field, as shown in Fig. 3, each length of conductor, or side of the coil, will pass entirely around the armature in $\frac{60}{N}$ seconds. The time taken for a conductor to pass through the magnetic field under each pole, or from a to b, is $\frac{60}{Np}$. Hence the average value of the electromotive force induced in each armature conductor as it passes under each pole is $\frac{Np\phi}{60 \times 10^8}$ volts, since a cutting of 10^8 lines per second gives one volt. Since in an actual machine the conductors are uniformly distributed around the surface of the armature, this is also the average voltage per conductor in each of the conductors between a and b at any instant. Since there are $\frac{Z}{m}$ conductors in series between the positive and negative brush sets, the average value of the total electromotive force between the brushes, when a suitable commutator (see below) is provided, is

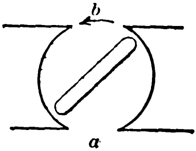

Fig. 3. Elementary Generator

$$E = \frac{p\phi ZN}{60 \times 10^8 m} \text{ volts.}$$

The electromotive force in each conductor alternates (i.e., passes through a complete cycle of positive and negative values) with a frequency of $f = \frac{pN}{120}$ cycles per second. Hence the formula for the average e.m.f. between brushes is

$$E = \frac{2 f\phi Z}{10^8 m} \text{ volts.}$$

The number of turns (S) in series between the positive and negative brushes is $Z/2m$, whence E may also be expressed as

$$E = 4 f\phi S \times 10^{-8} \text{ volts.}$$

Commutator. — A continuous electromotive force can be obtained from the machine if provision is made for reversing the connection from each conductor to the external circuit at the same time that the direction of e.m.f. induced in the conductor reverses. This is accomplished by the commutator. Taps leading from the front connections of the armature windings are connected to the segments of the commutator, so that as the segments come alternately under positive and negative brushes the current delivered to the circuit is always in the same direction.

ARMATURE WINDINGS. — Though there are a large variety of types of armature windings the practical man and even the designing engineer seldom meets types other than (1) the multiple-drum or lap winding and (2) the two-circuit series drum or wave winding. The other types may be used in a few special and exceptional machines but a designer may work for many years without finding any necessity for using them.

Multiple-drum or Lap Winding. — This type of winding is very common in direct-current machines, rotary converters, induction motors and is somewhat used in alternating-current generators. Its chief advantage is that it affords a

very free choice in the number of coils and slots, and is very simple to lay out and connect up. Its disadvantage is that it is not easily adapted to high voltages. Its chief characteristic is that there are always as many circuits in multiple and as many studs of brushes as there are poles. The distinguishing feature in appearance is the direction of bending of the end connections, as represented by Fig. 4. The characteristic form of the coils is shown in Fig. 7.

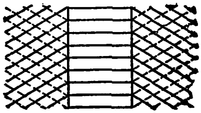

Fig. 4. Lap Winding

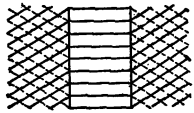

Fig. 5. Wave Winding

Conditions for Lap Winding.—The conditions to be fulfilled in laying out a simplex multiple-drum winding are expressed in the formula

$$Z = pz = sb,$$

where

Z = total number of coil-sides or bars,
p = number of poles,
z = average pitch* $= \dfrac{\text{front pitch} + \text{back pitch}}{2}$,
s = total number of slots,
b = number of coil sides or bars per slot.

The total number of inductors (Z) is double the number of coils, as each coil has two sides. Z must be a multiple of the number of slots (s) and of the number of poles (p).

The average pitch (z) must be an even number so that the front and back pitches may be different and odd ($z - 1$) and ($z + 1$), respectively. There are always two layers of coil-sides, top and bottom. One side of each coil lies in the top layer in one slot and in the bottom layer in another slot. The actual front and back pitches of a coil are always odd because they are made from a coil-side in the top layer (odd numbers) to one in the lower layer (even numbers) as in Fig. 6. Here the pitch is $14 - 1 = 13$.

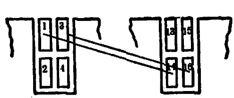

Fig. 6. Pitch of Connection

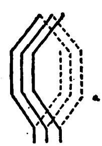

Fig. 7. Lap Winding

In order that the winding should progress continuously the front pitch, or pitch of commutator connections, must differ by one coil (or two coil-sides) from the back pitch, or actual pitch of coils. The actual spread of a formed coil (Fig. 7) is the same front and back and is equal to the "back pitch."

The total number of coils $Q = Z/2$ is equal to the number of commutator segments and must be a multiple of the number of slots. In general if Q is a common multiple of the number of poles and the number of slots, a multiple-

* Let the coil-sides be numbered consecutively from slot to slot, and let a point travel through the conductors in the order in which they are connected; if this point starting at conductor No. 1, say, passes through the point or (commutator) connection to conductor No. 8 and thus through the back connection to No. 3, then the front pitch is $8 - 1 = 7$ and the back pitch is $8 - 3 = 5$, and the average pitch is 6.

drum winding is possible. It is desirable that the number of slots should not be a multiple of the number of poles. In order to group the coils in polycoils z should be a multiple of the coil-sides per slot.

Series-drum or Wave Windings, Simplex. — This type of winding is used in direct-current armatures where the ordinary multiple drum would give either too low a voltage or require too many turns of fine wire in each coil. Its advantage is that it gives an armature that is better balanced magnetically and that only two brush studs are necessary. A greater number of studs may, however, be used. There are always two circuits in multiple, regardless of the number of poles. The characteristic reverse bends of its face conductors are shown in Fig. 5. The characteristic form of the coils is represented in Fig. 8.

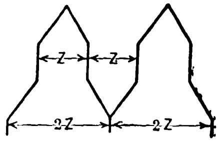

Fig. 8. Wave Winding

Conditions for Wave Winding. — The conditions to be fulfilled in laying out a series-drum winding are expressed in the formula

$$Z = pz \pm 2 = sb,$$

where

Z = total number of coil-sides or bars,
p = number of poles,
z = average pitch of end connections,
s = total number of slots,
b = number of coil-sides or bars per slot.

The total number of coil-sides (Z) is double the number of coils and must also be a multiple of the number of slots. In the formula $+ 2$ is preferable to $- 2$, as the positive sign gives shorter end connections.

The average pitch z may be odd or even. If it is odd the front and back pitches are both equal to z. If it is even the front and back pitches must be $(z-1)$ and $(z+1)$. For a wire winding the back pitch must be one greater than a multiple of the coil-sides per slot b in order to fit the coils into the slots in groups.

The total number of slots (s) is very much restricted and is intimately connected with the number of poles unless the expedient of using a dead coil is used (*see below*).

The bars or coil-sides per slot b must be even and cannot be 4 or 8 in a four-pole machine and cannot be 6 or 12 in a six-pole machine, unless a dead coil is used.

Use of Dead Coils. — By leaving one of the coils dead or out of circuit, a greater choice of slots and conductors is available. Four coil-sides per slot for 4 poles and 6 coil-sides for six poles may then be employed. In general $s \times b$ may be any number divisible by the number of poles. The formula is then

$$Z = pz - 2 = sb - 2.$$

Two bars or one coil are not connected in at all and the number of commutator segments is equal to the number of active coils or one less than the total coils. The total number of active coils is $Z/2$.

Usual Arrangements for 4- and 6-pole machines with no dead coil are:

Four Poles. — For $b = 6$, then z may be 1, 7, 13, etc., and usual values fulfilling all conditions are $s = 17, 21, 25, 29, 33$, etc. For $b = 10$, then z may be 1, 11, 21, etc., and s may be 19, 23, 27, 31, etc.

Six Poles. — For $b = 4$, then z may be 1, 5, 9, etc., and s may be 26, 32, 38, 44, etc.

Multiplex Wave Windings. — It sometimes becomes desirable to provide a winding which has more than two circuits in multiple but not as many as the number of poles. In such a case a multiplex wave winding would be selected. These are windings in which the circuit passes completely around the armature more than once. If to do this we use two entirely separate electric circuits we have a duplex doubly reëntrant winding, denoted by the symbol O O. If, on the other hand, the winding closes on itself after passing twice around the armature we have a duplex singly reëntrant winding, denoted by the symbol ◎. These types of windings are sometimes used when it is desired to have a number of circuits in parallel different from the number of poles. Thus we may have a six-pole machine with four circuits in multiple which with a given number of inductors would give a greater voltage than a multiple-drum winding and lesser voltage than a series drum. This would be a duplex winding.

Conditions for Multiplex Winding. — The conditions are imposed by the formula

$$Z = pz \pm 2m = sb,$$

where the symbols have the same meaning as before and m is the number of multiple windings and $2m$ the number of circuits in multiple. If m and z are prime to each other we have a singly reëntrant winding. The greatest common factor of m and z gives the number of times the winding reënters or in other words the number of independent windings.

The multiplicity and complexity may be carried to a very extreme limit. (*See under Armature Windings in any standard textbook.*) These multiplex windings are hardly ever used in the United States and England and only occasionally in Germany and France.

ARMATURE REACTION (OR ARMATURE INTERFERENCE). — The armature reaction of a d-c. machine has a very important influence on the commutation and regulation of both generators and motors. It is the effect of the magnetomotive force of the current in the armature conductors on the magnetic field set up by the field coils.

Separate Fluxes by Field and Armature Currents. — When current flows in the field coils and no current flows in the armature, a flux is set up following a path directly across the armature from pole to pole as in Fig. 9. On the other hand when current flows in the armature and there is no current in the field a flux is set up in the armature across the axis of the poles, as in Fig. 10.

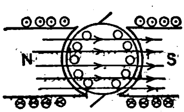

Fig. 9. Field Flux

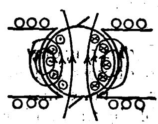

Fig. 10. Armature Flux

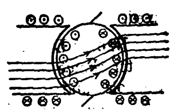

Fig. 11. Distorted Flux

Resultant Flux. — As a result of this action the flux is shifted around so that one tip of each pole has its density increased and one tip has the density decreased as in Fig. 11. If the brushes are at the geometrical neutral they are no longer on an axis at right angles to the flux; that is, they are no longer at the neutral point with respect to the resultant flux. With the brushes in this position the coil underneath a brush is cutting flux and generating a voltage, which is short-circuited by the brush and causes sparking. The brushes must, therefore, be moved a small angle in the direction of rotation in a generator (in the opposite direction in a motor) until they are on the neutral axis. The shift of the brushes aggravates the conditions, but nevertheless, unless the armature

strength is too great, a position can be found in which a brush short-circuits a coil that is in the real neutral position and is inactive.

Relations Shown Vectorally. — In Fig. 12 F_1 and A_1 are the m.m.f's. of the field and armature with the brushes on the geometrical or apparent neutral axis. R_1 is the resultant of these. The brushes which are in line with A_1 are not at right angles to R_1. If the brushes are moved to an axis at right angles to R_1 as at A_2, then the resultant becomes R_2 and the desired conditions have not been attained. By moving the brushes still further to A_3 giving the resultant R_3 we are able to get R_3 and A_3 at right angles to each other. The stronger the armature flux as compared to the field flux the greater will be the angle through which the brushes must be moved.

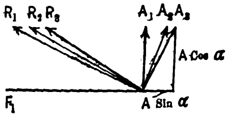

Fig. 12. Vector Relations of M.M.F.'s

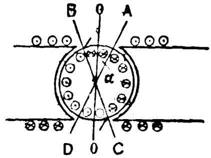

Fig. 13. Demagnetizing and Cross-magnetizing Turns

When the brushes are moved through an angle α to the position A_3 there is one component of the armature m.m.f., A sin α, directly opposed to the field m.m.f. Another component, A cos α, is at right angles to the field m.m.f. This is better understood by a reference to Fig. 13.

Demagnetizing Action and Cross-magnetizing Action. — Let the movement of the brush from A_1 to A_3 be represented in Fig. 13 by the movement from 0 to B, or through the angle α. Then the conductors in the angle 2α, between A and B and between C and D, carry currents whose m.m.f. directly opposes the magnetic strength of the field coils; these are known as back or demagnetizing conductors. The remainder of the armature conductors, in A–C and B–D, carry currents which give a m.m.f. at right angles to the field and cause a distortion of the flux; these are known as cross-magnetizing conductors.

It should be noted that while all the conductors in the sections A–B and C–D subtending an angle 4α constitute back ampere-turns, these are opposed to the strength of two poles. When we come to our quantitative treatment in which our unit of design is a pole we make use of the turns of 2α as the back ampere-turns per pole.

Effect of Interpoles on Armature Reaction. — The demagnetizing effect of armature reaction may be almost entirely overcome by placing the brushes in the neutral axis O–O. To prevent sparking under these conditions interpoles must be used. The use of interpoles does not in itself prevent armature reaction, but makes possible sparkless commutation when the brushes are set in such a position as to reduce armature demagnetization to a minimum.
